The reasons for the relatively lower bulkhead pressures can be due to one or a combination of the following factors: stope boundary effects, i.e. shear resistance along fill-wall interface, lower pore water pressure due to limited drainage at the bulkhead, and temperature effects.

The stope aspect ratio (stope length divided by stope width) of test 3 is the average of the first two tests. Similarly, the measured bulkhead pressure is also the average of the first two tests. Stope size, therefore, plays a significant role in the bulkhead loads. The smaller the stope aspect ratio, the higher is the bulkhead pressure.

The following changes were made to the filling procedures in the light of the pressure monitoring tests, for safer and more efficient filling practice.

- Fill the 7 m (2 m above the brow) first-stage height (plug).
- Decrease the fill rate from 0.43 to 0.35 m/h in the first stage.
- Increase the curing time from two to seven days for the plug.
- Fill the rest of the stope omitting the third stage.

These rules are applied to all stopes regardless of type. The safety measures that were introduced for blind stopes to avoid over pressurizing continued to be effective. The Cayeli Mine also moved away from using any waste rock for constructing bulkheads. All bulkheads are now constructed from reinforced shotcrete.

The pressure generation process is very complex and site-specific. Paste fill pressures depend on many factors such as tailings properties (type, particle sizing, and specific gravity), paste fill recipe (slump, solids content, and cement type and content), filling rate, filling placement sequence, and stope size and geometry.

Prior to the bulkhead failures, Cayeli shotcrete bulkheads were only designed for a maximum working pressure of 32 kPa. Fill placement was continuous and was managed by restricting rate of fill rise to a maximum of 0.43 m/h. The pressure-monitoring results, however, indicated that bulkheads could in fact be subjected to up to 100 kPa, even at the restricted fill rise rate of only 0.35 m/h.

These pressure monitoring results and conclusions drawn may not be applicable to other mining conditions. Bulkhead pressures are very site-specific and any bulkhead design should be based on actual pressure monitoring results.

TEMPERATURE MEASUREMENTS

Each pressure instrument had a built-in thermistor, which measured temperature variations during and after filling. Figure 13 shows the paste fill temperature profiles at the bulkhead and inside stope for test 3. Based on the temperature measurements, the following general conclusions can be made:

- Except for the first test, the paste fill temperature inside the stope is higher than the one at the bulkhead.
- The rate of fill temperature increase at the bulkhead is lower than that measured inside the stope.
- The fill temperature inside the stope increases by about 16 degrees over five days.
- The fill temperature decrease after five days.
- The rate of temperature drop is slower and similar in magnitude both at the bulkhead and inside the stope.

Fig. 13. Measured paste fill temperature profile for test 3.

Furthermore, ignoring the effect of nearby mining, the following temperature effects were observed from tests 2 and 3:

- During the plug cure time, pressures increase in response to temperature increase.
- After filling is completed, pressures drop in response to temperature drop.

Measured Cayeli paste fill uniaxial compressive strength values are typically less than 100 kPa at five days cure age. The temperature effects during the first five days will therefore be limited due to low deformation modulus of paste fill compared pressure cell stiffness. Measured pressure readings reported in this paper are therefore not corrected for temperature effects.

CONCLUSIONS

Paste backfill is an integral part of the mining method at the Cayeli Mine. Safe and efficient placement of paste fill requires a detailed understanding of paste fill characteristics, from the production stage to the final fill exposures.

Mobilization of uncured paste fill as a result of a bulkhead failure is a potential safety hazard and can lead to significant consequences, including endangering the safety of personnel, property damage, and production losses and delays.

Since inception of paste filling operations in 1999, there have been three major bulkhead failure incidents at Cayeli. Detailed descriptions of each of these incidents and their consequences have been provided in order to raise general awareness among backfill practitioners and mine operators about the potential risks associated with bulkhead failures.

Bulkhead failure investigations revealed that in all cases failure occurred in small and blind stopes during last stage of filling while tight filling. Furthermore, stopes were overfilled by about 10% and there were problems with air relief holes.

These bulkhead failures were attributed to one or a combination of the following factors: fast filling rate; continuous filling or inadequate plug fill cure time; 'overfilling' during the tight filling stage due to the absence, blockage or inadequate use of air breather holes; lack of adequate fill management and fill monitoring controls; and inadequate bulkhead design.

As a direct outcome of bulkhead failures, the Cayeli Mine moved away from using any waste rock for constructing bulkheads. All bulkheads are now constructed from reinforced shotcrete.

Cayeli Mine gained invaluable information about the development and magnitude of pressures inside and behind the bulkheads through a detailed field pressure-monitoring program. Cayeli instrumentation and monitoring program indicated that the loading conditions in the paste fill and the resultant lateral loads on the bulkheads are complex and are dependent on many factors, such as tailings properties (type, particle sizing, and specific gravity), paste fill recipe (slump, solids content, and cement type and content), filling rate, filling placement sequence, and stope size and geometry.

Based on the Cayeli pressure monitoring test results, the following general conclusions can be drawn:

- Despite the same fill recipes and fill rise rates used, bulkhead pressures were significantly different. The difference is attributed to different stope size and filling sequences.

- Continuous filling with no cure time leads to higher bulkhead pressures. This is due to the higher pore water pressure and slower pore water pressure dissipation with ongoing filling.
- At the same fill rise rate, staged filling results in lower bulkhead pressure. This is attributed to the higher fill strength in the plug fill. The rest time enables pore water pressure dissipation and longer fill cure times. The weight of ongoing filling is partially distributed to the stope sides as a result of arching.
- Temperature changes during cement hydration can have an impact on the pressure readings. Test results indicate that an increase in temperature increases pressure and a decrease in temperature decreases pressures.

Prior to the bulkhead failures, Cayeli shotcrete bulkheads were only designed for a maximum working pressure of 32 kPa. Fill placement was continuous and was managed by restricting rate of fill rise to a maximum of 0.43 m/h. The pressure-monitoring results, however, indicated that bulkheads could in fact be subjected to up to 100 kPa even at the restricted fill rise rate of only 0.35 m/h.

Based on the evaluation of pressure monitoring test results and findings from the bulkhead failures described in this paper, the Cayeli Mine has made the following design and operational changes in their paste fill system: revised shotcrete bulkhead design, new fill recipe, revised fill placement procedures, and new fill risk management and monitoring procedures. Site-specific new operating practices are now in place that allow safe and efficient fill placement.

To date, Cayeli has filled more than 50 blind stopes without any failure incidents. The new bulkhead design and fill placement sequence has therefore been proven to be successful.

Going forward, the Cayeli Mine is considering instrumenting every single bulkhead with a pressure cell, transferring the pressure data to the paste plant and filling until a threshold bulkhead pressure is reached. More pressure tests are planned for this purpose and they are ongoing. The mine is also looking to automatically monitor the airflow in blind stope breather holes as an indicator of potential over-pressuring.

In conclusion, this case study shows that only a combination of properly engineered bulkhead design, bulkhead construction, and better management of fill placement can provide safe and efficient filling practices. Furthermore, bulkhead pressures are very site-specific and any bulkhead design should be based on actual pressure monitoring results.

ACKNOWLEDGMENT

The authors would like to thank the management of the Cayeli Mine for allowing the use of the data and encouraging the publication of this paper. Thanks are also due to the mine and engineering staff for their help during the collection of the data. The authors are also grateful to the management of AMC Consultants for the motivation and help during the preparation of this paper.

Paper reviewed and approved for publication by the Minefill 2007 review committee.

Mehmet Yumlu is a Professional Mining Engineer who graduated from Middle East Technical University in Ankara, Turkey, in 1991. He also holds an M.Sc. degree in rock mechanics from the University of Witwatersrand. From 1992 to 1998, he studied and worked in various rock mechanics roles in South Africa. In late 1998, he joined Inmet Mining Corporation's Cayeli Mine in Turkey where he worked as a chief mining engineer until February 2005. In March 2005, Mehmet moved to Australia to join AMC Consultants Pty Ltd., where he is now a principal mining engineer at the company's Melbourne office.

Murat Guresci received a B.Sc. degree in mining engineering from Hacettepe University, Ankara, Turkey, in 1999. After graduation, he worked as a shift engineer at Bauholding Strabag AG in the construction of the Muratli Dam & Hydro Electrical Power Plant in Artvin, Turkey, prior to joining Cayeli Bakir Isletmeleri A.S. (Inmet Mining Corporation) in 2003 as a rock mechanics engineer.

Memo

To:	Lyle Morgenthaler	**Date:**	February 12, 2018
Company:	Pretium Resources Inc.	**From:**	Denis Thibodeau
Copy to:		**Project #:**	5CP007.000
Subject:	Waste Fill Fence Design for Paste Fill		

Introduction

Pretium Resources Inc. (Pretium) requested SRK Consulting (Canada) Inc. (SRK)'s assistance in the design of a fill fence used as a barricade for paste fill of mined stopes at its operating Bruce Jack Mine. The fill fence would be constructed with waste rock material generated from development extraction. Pretium's mining method consists of either transverse or longitudinal long hole stoping. SRK is to provide a waste fill fence design to meet the current requirements for shotcrete fences when 200 KPa of lateral pressure is applied.

Methodology

To design a waste fill fence for application at the Bruce Jack Mine, the fence demand must first be understood. The demand consists of the lateral pressure applied by the paste fill column on the fence. Pretium's current practice is to pour a paste fill plug at 11 % binder reducing over time to original design specifications to a maximum height of 10 m and pour the remainder of the stope with 6.4% binder. The initial design for shotcrete fences considers a maximum lateral pressure of 200 KPa.

Therefore, calculation was made for 200 KPa lateral pressure (Pa).

The capacity of the waste fill fence will depend on the shear resistance of the waste material against the lateral pressure from the paste fill column. The resisting contributing force must take into account the shear against the floor and the walls of the drift. The friction against the back is not considered due to poor contact between the waste barricade and the back. It is expected that the friction between the waste, and the walls, floor and back of the drift, will be greater than the internal friction of the waste due to drift profile irregularities, therefore the internal friction of the waste material will be assumed for the calculations.

According to Aubertin et al, 2009 considering a worst case scenario of waste fence being fully saturated with water, the fill fence requirement is calculated as follows:

Equation 1: $\mathbf{L} = \frac{\mathbf{p}}{\boldsymbol{\lambda}}$

Where:

L is the required length of waste fence
P is the maximum lateral pressure: 200 KPa

l is equal to Equation

Equation 2: $\boldsymbol{\lambda = \mathrm{Tan}\varphi K_R\left(\gamma_\omega h + \frac{\gamma_s - 2\gamma w}{3} h\right) h}$

$$+ \mathrm{Tan}\varphi\left(\gamma_w h + \frac{\gamma s - y_w}{2} \cdot h\right) w$$

$$+ \mathrm{Tan}\varphi K_R \gamma w\left(\frac{h^2}{3}\right)$$

Where:

γw Is the unit mass of the waste fill: 1,800 kg/m^3 (Pretium internal communication)
γs Is the unit mass of the saturated waste fill: 2,050 kg/m^3 (assuming 25 percent void) – unit weight of water 1000n/m^3)

h is the height of waste material corresponding to drift height of 5 m (Pretium internal communication)
f is the internal friction angle of the waste material: 30°

K_R is a coefficient of friction $= \frac{1-\sin\varphi}{1+\sin\varphi}$

Therefore, for a maximum lateral pressure of 200 KPa the fill fence barricade with a safety factor of 1.4 = 0.77 m.

Conclusion

Based on the waste material characteristics, and the lateral pressure expected and/or measured on the current shotcrete fill fence provided by Pretium, the length of the waste fill fence was calculated for 200 kPa. The minimal length of waste fill fence calculated is 0.77 meter. The field length requirements are set to 5 meters from toe to toe. A minimum 1 meter length of waste and/or shotcrete must be in contact along the back of the drift due to variable inherent to the waste material. Shotcrete is required for gap filling between the waste pile used to create the fence and the back of the mucking drift. The provided waste fill length is valid only for a paste fill plug pour to a maximum height of 10 m above the stope floor. The plug must cure to withstand a 20 meters high fill pour for the remainder of the stope. To minimize leakage, the toe of the waste pile must be shotcreted with a minimum 50 mm thick coat. The plug pour is required since the waste fill fence design provided will not resist the lateral pressure generated by the full column height of the paste fill of 30 m. For the Bruce Jack Mine, the waste fill fence is designed for a maximum lateral pressure of 200 KPa.

Recommendations

SRK recommends the following:

1. Use a minimum 5 m length waste fill fence from toe to toe.
2. Ensure a minimum contact of 1 m in the back.
3. Fill any gap between the back and the waste fill fence with shotcrete
4. To avoid leakage cover the toe of the barricade with shotcrete with a minimum thickness of 50 mm.
5. While pouring plug follow SOP BRUCEJACK-UND-SAF-004.

Appendix N
BJ-ENG-SOP-033 Rock Barricade Construction

Objective

The objective of this procedure is to provide direction, information, and controls for rock barricade construction to build and maintain the integrity of the earth fill structure throughout the stope paste backfilling process.

Ensure all workers understand the hazards and are qualified with the skill and competency needed to be working in a responsible and safe manner near the open stopes.

Scope

As longhole stopes are mined out, barricades are erected to dam stopes for paste backfill deposition. Rock barricades (also referred to as “muck barricades”) and Shotcrete Arch Fill Fence (SCAFF) barricades are the two methods employed at Brucejack mine. Rock barricades are chosen for most stopes, owing to the reduced time and cost required to construct them. The construction of these rock barricades is the subject of this SOP.

Additionally, monitoring instruments such as Total Earth Pressure Cells (TEPC) are occasionally installed in stopes with rock barricades specified for construction. The specific complications associated with the installation of these sensors is also covered in this procedure. Proper installation is critical to the collection of data to further our understanding of paste backfill pressures. This has potentially significant impacts on process improvement and cost savings.

This standard operating procedure will be applied by all personnel who are involved in the process of barricade design, material handling, preparation work, construction, and inspections, including both Pretivm employees and subcontractors, to ensure the construction of robust rock barricades.

Health, Safety & Reclamation Code of BC

- Working Conditions – 1.9.1
- Examination of Workings – 6.4.1
- Workplace to be Hazard Free – 2.2.1

Definitions

- Rock Barricade – the earth gravity structure which is constructed in front of draw points to contain the paste in stope.
- Open Brow – the interface between the stope void and the draw points
- LHD (scoop) – a machine used to load, haul and dump the muck into another location.
- PPE – Personal Protective Equipment
- CMS – Cavity Monitoring System
- TEPC – Total Earth Pressure Cells, an instrument to monitor the pressure of the paste.
- SCAFF – Shotcrete Arch Fill Fence, an alternative stope barricade option.
- Metal frame – a customized angle steel piece which is designed to accommodate TEPC instrument(s).
- Limited Zone – the area between 2m from the brow/edge and beginning of the respective safe zone for equipment only (no personnel).

Preparation

Hazards

- Energized equipment
- Poor visibility
- Potential bouncing rock from in-stope, sloughing rock from muck pile

- Poor ventilation
- Barricade failure
- Ground failure
- Tripping / slipping hazards

Tools

- Underground LHD loader
- Rammer Jammer
- Underground Rock Truck
- Telehandler
- Spray paint
- PPE – hardhat, safety glasses, miner's belt with W65, safety boots with metatarsal protection, and hi-visibility coveralls.

Requirements

- Underground operators, engineers, Procon supervisors must review this SOP and drawings issued by site geotechnical team before commencing rock barricade construction.

Responsibilities

Mine Manager

The Mine Manger is responsible for:

- Ensuring this procedure is implemented and maintained.

Geotechnical Engineer

The Onsite Geotechnical Engineer is responsible for:

- Inspecting the ground condition at the draw point and surrounding area.
- Marking up the location of the rock barricade(s).
- Developing a drawing with specifications for the rock barricade construction.
- Communicating the design drawing with the underground personnel and Procon supervisors.
- Implementing this procedure.
- Conducting field inspections after each stage is completed to ensure it meets specification.
- Working together with underground operations personnel as needed during TEPC installation.

Procon Supervisors

Procon Supervisors are responsible for:

- Ensuring that stope has been signed off as complete by Pretium geologists and CMS scan is also completed.
- Implementing this procedure with the combination of design drawing issued by onsite geotechnical engineer.
- Assigning this task to a more experienced operator, or spending adequate time training, checking up on, and verifying the work of less-experienced barricade construction operators.
- Reviewing the potential hazards with underground operations personnel.
- Checking that underground operations personnel are adhering to the procedures.

Underground Operations Personnel

Procon Underground Operations Personnel are responsible for:

- Adhering to this procedure at all times.
- Performing visual ground condition inspections, equipment pre-shift inspections, and PPE inspections.
- Safely operating LHD, Rammer Jammer and telehandler, when needed.
- Keeping all barricades and signage properly placed and maintained.
- Stopping work and retreating to a safe area if conditions are changed.
- Immediately reporting any substandard ground conditions to their supervisors.
- Asking for clarification from supervision if they have questions or concerns.
- Ensuring that the integrity and dimensions of the rock barricade built meets the standard of the design.
- Ensuring that the TEPC instrument wires are protected and undamaged during sensor installation and subsequent rock barricade construction.

Health and Safety Manager

The Health and Safety Manager and their designate(s) are responsible for:

- Monitoring the implementation of this procedure.
- Maintaining training records.

Job Step

Regular Rock Barricade Construction:

Step 1:

Onsite geotechnical engineer will inspect the walls, back, and open brow ground condition and break through holes from stope before marking up the location of the rock barricade. Figure 1 illustrates the example of how the location of the tight back and the toe line will be marked up in the field. A detailed and design-specific drawing for the rock barricade construction will be issued to Procon supervisors and underground operations personnel.

Figure 1

Step 2:

To start off the construction with waste rock as shown in Figure 2, use LHD scoop to dump muck close to the brow of stope and build up the pile; use rammer jammer to push muck towards the first line of the tight back.

Then dump some finer rocks or paste materials to build the thin layer against the initial muck pile. Ensure it is also tight to back as much as possible.

Figure 2

Step 3:

Continue with the rock barricade construction with waste rock. Use the rammer jammer to ensure the total distance of tight back is 5 m. Ensure the toe of the rock barricade has reached or slightly exceeded the toe line which was marked up by geotechnical engineer. The maximum gap distance between back and rock barricade is less then 6 inches. Onsite geotechnical engineer will conduct the first visual inspection once this step is completed.

Figure 3

Step 4:

Upon approval from onsite geotechnical engineer, apply a 5 cm (2”) thick layer of shotcrete to cover the face and top gap of rock barricade. 24 hours curing time is required. Onsite geotechnical engineer will conduct the final visual inspection.

Figure 3

Step 5:

Ensure to place safety berm catchment as well as proper signage and barricade after rock barricade construction and shotcrete are complete. Only if both final inspection and cured shotcrete are met, paste filling can be started.

Figure 4

Step 6 (Optional Step 1):

In the case muck berm tight back is less than 3m due to short distance from stope brow to main drift, intersection for other cross cuts and/or hammer head drifts for resue drilling, initial muck berm should be built with tight back from brow to the intersection as much as possible then apply a 5 cm (2”) thick layer of shotcrete to cover the face and top gap of rock barricade. 24 hours curing time is required. Onsite geotechnical engineer will conduct the visual inspection on shotcrete condition. Minimum 200 ton of additional muck need to be placed in front of SC sprayed berm to provide additional load against paste fill pressure.

Step 7 (Optional Step 2):

In the case muck berm tight back is less than 3m and equipment resources are not available for Step 6 (Optional Step 1), maximum stand-off distance need to be estimated by Geotechnical Engineer based on estimated sill paste volume and Mine Production Engineer should check possible damage of underground infrastructure within stand-off distance. This step only can be conducted under approval by Pretivm Mine Superintendent.

Rock Barricade Construction with Total Earth Pressure Cell (TEPC) Instruments Installation:

Both underground operation personnel and onsite geotechnical engineer must establish good communication about materials handling, instrument installation and rock barricade construction process beforehand. In addition, both parties should be present during construction. The detailed steps are as follows:

Step 1:

Geotechnical engineer will check to see if the instruments planned for installation function in the main office with the data loggers. Ensure to record the instrument IDs as well as apply calibration factors as possible before leaving the office.

Step 2:

Instrument wires need to be covered with 1.5’’ yellow service hose or PVC pipe by connecting to the instrument wires with a master cord, then pulling out from the other end. The PVC pipe should be flushed against the instrument with some slack as do not want to apply too much tension on to the wires. The required length of PVC pipe is at least 15m. This is to prevent rock damage to the fragile instrument wires during the construction.

The data logger and wire spool should be situated in a safe location for readings away from the line of fire, and an area where it may not get damaged by equipment or personnel (labelling is key).

Place the metal frame with instrument about 4-5m passing the brow into the open stope by using a telehandler with forks and ensure the ground chosen for placement is solid and even. All installations and preparation work must be done in a safe zone.

Run the PVC pipe with caution through the back and extend it further to the toe line (Figure 6); hang it on the screens with straps, securing the pipe to the screen every 1-2 m. All wires should be protected, properly labelled and the metal frame sitting rigidly on the flat ground inside the stope. At this point, start pushing muck and build the first pile. It's important to build the initial pile with caution as muck rolling over and into the stope may hit the metal frame and/or damage the instrument. Use rammer jammer to push muck towards the first line of the tight back.

Dump some finer rocks or paste materials to build a thin layer of fines against the first stage of muck pile as shown in Figure 6. Ensure this and the coarser muck beyond it is as tight to the back as possible.

Figure 6

Step 3:

Continue with the rock barricade construction. Use the rammer jammer to ensure the total distance of tight back is 5 m or greater. Ensure the toe of the rock barricade has reached or slightly exceeded the toe line which was marked up by geotechnical engineer. The maximum gap between the back and the top of the rock barricade is 6 inches (Figure 7). Onsite geotechnical engineer will conduct the first visual inspection once this step is completed. If any worry exists, one can verify the sensor wire integrity with the datalogger(s) now as well.

Figure 7

Step 4:

Upon approval from onsite geotechnical engineer, apply a 5 cm (2") thick layer of shotcrete to cover the face and top gap of rock barricade (Figure 8). Avoid spraying shotcrete to the exposed wires without PVC casing protected as they are fragile. 24 hours curing time is required. Ensure to place safety berm catchment as well as proper signage and barricade after rock barricade construction and shotcrete are complete.

Onsite geotechnical engineer will conduct the final visual inspection. Only if both final inspection and cured shotcrete are met, paste filling can be started. Geotechnical engineer will also ensure that the instruments are set to start the data collection by using data logger, including verifying that the correct unit and calibration factors are applied.

1 Introduction

1.1 Overview of Proposed Production Increase

Pretium Resources Inc. (Pretivm) is proposing to increase the authorized Brucejack Gold Mine ore production rate from an annual average 1.0 Mt to 1.4 Mt (i.e., average 2,700 tpd to average 3,800 tpd). The production increase application also reflects an increase in the mine ore reserves, from 16.5 Mt for the 2015 MA-EMA Permits Application, to 18.5 Mt. The increase in the ore production rate will reduce the mine life from 18 years as predicted in 2015, to approximately 14 years, with the ore reserve increase slightly offsetting the mine life reduction.

Also integral to the applications is that Pretivm is seeking authorizations for the flexibility to direct waste rock to either Brucejack Lake, or as backfill in the underground mine, depending upon operational needs. Specifically, Pretivm is applying for authorizations to deposit between 36% and 100% of future waste rock in Brucejack Lake, to provide operational flexibility for mine waste deposition. These percentages of waste rock to be deposited subaqueously are based on the following two scenarios:

- Scenario 1, which assumes that all waste rock going forward (5.3 Mt) and 50% of the tailings (8.7 Mt) would be deposited subaqueously in Brucejack Lake, with the remaining tailings (8.7 Mt) paste backfilled in the underground mine; and
- Scenario 2, which assumes maximum backfilling of waste rock in the underground mine (3.4 Mt), with the remaining 1.9 Mt deposited in Brucejack Lake. Consequently, significantly less tailings would be backfilled as paste in the underground mine (5.5 Mt; 32% of total generated).

The approach in evaluating these scenarios is that if both waste rock deposition extremes are acceptable for a given assessment, any ‘in-between’ waste rock deposition would also be acceptable. Build-out figures, illustrating both Scenario 1 and 2, are presented as Figure 1 and Figure 2 respectively.

1.2 Scope

SRK Consulting (Canada) Inc. completed the original subaqueous waste rock and tailings deposition design and management plan included as Appendix 6-O of the 2015 Brucejack Gold Mine MA/EMA Permits Application (Pretivm 2015). This management plan is consistent with the waste rock and tailings deposition design report produced by SRK (SRK 2016a). SRK has acted as Engineer-of-Record (EOR) for the waste rock dump (WRD) since the start of construction in 2016 and continues to act in that capacity at the time of writing this report.

This report provides a design update of the WRD taking into consideration the proposed production increase. It demonstrates that the proposed increased deposition scenarios would not impact the overall WRD performance, and that the WRD procedures as outlined in the current dumping Standard Operating Procedure (SOP) (SRK 2017, Appendix A-1) remain valid. It furthermore demonstrates that the current Quantifiable Performance Objectives (QPOs), as outlined in the current Operations, Maintenance and Surveillance (OMS) Manual (SRK 2017) remain appropriate to ensure safe operation and overall stability (short and long term) of the WRD.

2 Historic Waste Rock Dump Design

2.1 Previous Design

The previous WRD design is documented in SRK (2016a), which is a comprehensive tailings and WRD design report prepared by the EOR. Specifically, this design report includes an Appendix (Appendix C; SRK 2014) which documents the Brucejack WRD stability and settlement analysis. This analysis takes into consideration site specific physical characterization of the lake bed sediments, the lake bathymetry, and measured lake bed sediment thickness.

This design report also includes another Appendix (Appendix A, SRK 2015a) that describes the rheological properties of the tailings. These data confirm that based on physical characteristics of the tailings, the tailings is predominantly silty-sand, while the lake-bed sediments range from sands to fine clays, including silty-sands. Although WRD stability analysis was not completed assuming tailings as a foundation material, the range of lake bed sediment properties used in the analysis more than adequately covers the tailings material behaviour.

2.2 Design Criteria

No prescribed stability requirements are available for subaqueous waste rock deposition in British Columbia (or globally). However, the “Mined Rock and Overburden Piles Investigation and Design Manual” (BCMWRP 1991) can be used as a starting point to inform a possible minimum acceptable Factor of Safety (FoS).

Table 1 presents the recommended FoS, based on levels of confidence in the understanding of site conditions, material parameters and the consequences of instability in accordance with BCMWRP (1991). In the context of the Brucejack WRD, Case B is considered the most representative case.

Table 1: BC (Subaerial) Mined Rock and Overburden Pile Minimum FoS Guidelines

Stability Conditions	Suggested Minimum Design Values for FoS	
	Case A	Case B
Stability of Dump Surface		
Short-term (during construction)	1.0	1.0
Long-term (reclamation – abandonment)	1.2	1.1
Overall Stability (Deep Seated Stability)		
Short-term (static)	1.3 – 1.5	1.1 – 1.3
Long-term (static)	1.5	1.3
Pseudo-static (earthquake)	1.1 – 1.3	1.0
1. Case A • Low level of confidence in critical analysis parameters • Possibly non-conservative interpretation of conditions or assumptions • Severe consequence of failure • Simplified stability analysis method (charts, simplified method of slices, etc.) • Stability analysis method poorly simulates physical conditions • Poor understanding of potential failure mechanism(s)		
2. Case B • High level of confidence in critical analysis parameters • Conservative interpretation of conditions, assumptions • Minimal consequence of failure • Rigorous stability analysis method • Stability analysis method simulates physical conditions well • High level of confidence in critical failure mechanism(s)		

2.3 Previous Design Analysis Results

The previous design confirmed that physical stability of the Brucejack WRD results in inherently low FoS' when compared to BCMWRP (1991). Fundamentally, it was determined that the active dumping face of the Brucejack WRD remains in a quasi-stable state with a FoS near unity for a period of weeks to months depending on the thickness of the unconsolidated undrained and highly variable lake bed sediments, until sufficient pore pressure dissipation has occurred to allow the WRD foundation to carry the load of the WRD and remain stable.

2.4 Design Approach

Because the design analysis confirmed that a conventional FoS approach, based on numerical analysis would not allow for construction of the WRD, the observational method (Terzaghi and Peck 1967, Peck 1969) was adopted as the design approach for the Brucejack WRD. This method was developed from the need to avoid highly conservative assumptions about ground properties in geotechnical design when faced with unavoidable uncertainties of natural ground conditions. It takes advantage of observations and data gathered during construction to adapt the design to actual ground conditions in an orderly and planned way. Implementation of this approach in the context of the Brucejack WRD requires the following:

- Conduct numerical analysis to establish behavioral bookends;

- Develop monitoring requirements to allow behavioral tracking;
- Develop and implement safe operating procedures for WRD construction;
- Develop QPOs to inform safe operating procedures;
- Conduct ongoing monitoring and reanalysis as necessary; and
- Continuously revisit and update safe operating procedures as necessary.

As a result, strict operational controls were set to ensure safe WRD construction. This rigorous dumping procedure allows for sufficient safe preloading of the foundation, subject to continuous monitoring and review by a qualified geotechnical site engineer, with ongoing oversight by the EOR, and annual independent geotechnical inspections by an external geotechnical engineer. This dumping procedure is independent of the lake bed sediment thickness or strength, because it is based on the assumption that the foundation cannot initially carry the load whether it is due to sediment thickness or strength (or both). This is documented in the OMS Manual (SRK 2017) which includes the current SOP (SRK 2017, Appendix A-1).

3 Historic Waste Rock Dump Performance

Consistent with the observational approach, the OMS Manual and the dumping SOP are living documents which has been updated multiple times as the WRD behaviour understanding is improved. Specifically, three incidents, as described below has resulted in changes over the life of the WRD construction. Other factors that have resulted in changes to the dumping procedures include routine operational efficiency reviews, such introduction of the stacker system.

3.1 October 2015 Incident

On October 11, 2015 a substantial foundation failure occurred during construction of the WRD. A follow-up investigation (SRK 2015b) confirmed that failure was most likely a complete foundation (i.e. bearing capacity) failure as a result of loading the foundation too fast, thereby not allowing sufficient preloading time for pore pressures to dissipate. The dumping rate at the time was in excess of 10 times that recommended in the design.

A subsequent back analysis of the failure (SRK 2015c) confirmed the failure was a foundation failure and the foundation sediment types were a normally consolidated fine grained silty material. During rapid loading of the dumping face, the silty sediments reached their maximum shear strength under undrained conditions. Very importantly, the back-calculated material properties were in good agreement with the values of the undrained shear strength of the silty and clay materials used in original design (SRK 2014) providing confidence in the expected design performance.

3.2 April 2016 Incident

A fairly substantial outer slope sloughing failure of the WRD occurred on April 3, 2016. A thorough investigation of this failure (SRK 2016b) concluded that multiple different factors likely contributed to the failure, but that fundamentally the failure mode was expected and consistent with the original dump design (SRK 2014). Importantly, a crusher that was temporally installed and operated near the WRD face was believed to be at least in part responsible for the failure. The incident led to minor refinements of the dumping SOP, the most significant being increasing the overall crest setback distance.

3.3 June 2016 Incident

On June 6, 2016 a substantial portion of the WRD sloughed and almost breached the pre-loading berm that demarcates the deemed safe zone (i.e. setback distance) of the dump. Detailed analysis of the incident revealed (SRK 2016c) that because surface rock excavation for mine construction was almost complete by that time, the waste rock composition had changed to consisting predominantly of underground mine muck. The underground mine muck contains significantly more fines than the surface waste rock (partly due to different blasting techniques in the underground mine compared to surface), and those fines affect the overall dump behaviour. This incident resulted in Pretivm adjusting the dumping strategy to include a conveyor stacker, and subsequently adjusting the dumping SOP (SRK 2017, Appendix A-1) to allow mine muck smaller than 8 inches to be dumped using the stacker, while larger materials are dumped in accordance with the original dumping SOP. Pretivm continues to evaluate alternatives to stacker use, and if suitable alternatives are identified in future, Pretivm would seek to revise the OMS Manual (SRK 2017) as applicable.

4 Updated Waste Rock Dump Design

Consistent with the observational approach, SRK has revisited the WRD design to confirm whether the proposed expansion would result in any changes to the safe operation of the WRD, and whether the current OMS Manual, SOP and associated QPOs require modification. This section of the report describes the numerical analysis that was completed to assess the WRD stability in its current state, as well as in future as the dump extends further into the lake. Furthermore, this numerical analysis is evaluated against observational data of the WRD performance.

4.1 Stability Analysis

4.1.1 Objectives

A stability analysis of the WRD was completed at the most critical cross section to evaluate the risk during construction related to catastrophic dump failure. This approach inherently implies that the resultant outcome is conservative, as in every other location of the dump conditions are better. This numeric analysis should not be viewed in isolation, as it needs to be evaluated in the context of field observations (visual observations and displacement measurements), which are dicussed in the next chapter.

4.1.2 Geometry

The location and geometry of the adopted cross section for the stability analysis are shown as Section A in Figure 3. This cross section was selected as the critical section for the analysis based on the foundation conditions (inclination and thickness of the fine-grained materials). The downstream slope of the dump is approximated as 1.5H: 1.0V (Horizontal: Vertical).

It should be noted, that in reality the outer slope does undergo continuous sloughing and as a result in all likelihood the outer slope is expected to be flatter, but sufficiently detailed bathymetric survey to definitively confirm this is not available and therefore the analysis is completed with the more conservative steeper slope.

4.1.3 Material Properties

Table 2 lists the material properties used in the stability analysis. Friction angles were based on direct shear tests results (BGC 2014, as reported in SRK 2014). The undrained shear strength to effective stress ratio s_u/σ_v' obtained during triaxial testing (BGC 2014, as reported in SRK 2014). Failures are not expected to occur through bedrock as it has been characterized as strong and competent, especially in comparison to the weak, unconsolidated foundation materials, therefore it was assumed to have infinite strength.

The soil at the foundation was assumed to be composed of uniform clay, a conservative assumption when compared to the original stability analysis (SRK 2014). A sensitivity analysis was performed increasing the clay strength parameters as indicated by the values between parentheses in Table 2.

The presence of tailings at the toe of the dump was considered for the final expansion of the WRD. The material properties of these tailings were adopted in a conservative manner based on engineering judgment.

Table 2: Material Properties used in Stability Analysis

Geotechnical Unit	Unit Weight, γ (kN/m^3)	Cohesion, c (kPa)	Friction Angle, ϕ (º)	Undrained Shear Strength, s_u (kPa)
U1: Waste Dump	22.0	0.0	38.0	NA
U2: Clay	16.0	0.0 (0.0)	27.0 (30.0)	$0.27\times \sigma_v'$ $(0.30 \times \sigma_v')$
U3: Bedrock	26.0	Infinite Strength		
U4: Tailings	16.0	0.0	27.0	NA

Note:

Values in parenthesis are increased shear strength parameters of clay for sensitivity analysis purposes.

4.1.4 Results

Table 3 summarizes the result from the stability analysis. The first column refers to the geometric configuration of the dump used in the analysis. The dump configuration is defined as the advance distance of crest measured from the current position (e.g., a distance of 42 m indicates that the dump crest has advanced 42 m into the lake with respect to the position it had at the time of writing this report).

The second column indicates whether the shear strength of the clay was considered under drained or undrained conditions. The third column refers to the type of slip surface analyzed with the software, either circular (rotational) or non-circular (translational). Column (4) in Table 3 includes the calculated setback distance measured from the crest to get a FoS > 1.1; i.e., all slip surfaces of the analysis outcropping beyond this distance have a FoS > 1.1. Setback distances to get a FoS > 1.3 are included in column (5). Values in parenthesis in columns (4) and (5) are setback distances for the increased shear strength parameters of the clay included in Table 2.

The sixth column is the minimum factor of safety calculated for the corresponding scenario. The seventh column is a description of the critical slip surface (i.e. the one with the lowest FoS): in the “Shallow Slope” type, the slip surfaces is within the dump and does not include the foundation; in the “Shallow Slope-Toe” type, the slip surface does not go to the crest of dump and is concentrated between the foundation and the toe of the dump; in the “Slope-Foundation” type, the slip surface is a deep seated one involving the dump from the crest to its foundation; and the ”Slope-Tailings” type is the same as the “Slope-Foundation” type when the dump is founded in tailings. Figure 4 illustrates these failure types.

The values between parentheses in the fourth, fifth and sixth column are the corresponding results for the increased shear strength parameters of the clay (shown between parentheses in Table 2).

The failure mechanisms and setback distances for each of the analyzed scenarios are shown in Figures 5 to 12.

Table 3: Summary of Results from Stability Analysis

(1) Scenario	(2) Loading Condition	(3) Failure Mechanism	(4) Set Back (m) for FoS > 1.1	(5) Set Back (m) for FoS > 1.3	(6) Minimum FoS	(7) Failure Type at Minimum FoS
Current condition	Drained (Figure 5)	Rotational	8 (8)	25 (25)	0.91 (1.00)	Shallow Slope-Toe
		Translational	22 (13)	40 (31)	0.92 (1.01)	Shallow Slope-Toe
	Undrained (Figure 6)	Rotational	76 (59)	111 (76)	0.65 (0.71)	Shallow Slope-Toe
		Translational	95 (86)	125 (112)	0.65 (0.71)	Shallow Slope-Toe
Crest ~42 m from the current condition	Drained (Figure 7)	Rotational	0 (0)	13 (13)	1.01 (1.10)	Slope-Foundation
		Translational	12 (0)	33 (29)	1.01 (1.10)	Slope-Foundation
	Undrained (Figure 8)	Rotational	90 (13)	105 (105)	0.70 (0.76)	Slope-Foundation
		Translational	30 (27)	47 (43)	0.76 (0.81)	Slope-Foundation
Crest ~84 m from the current condition	Drained (Figure 9)	Rotational	0 (0)	20 (10)	1.18 (1.18)	Shallow Slope
		Translational	0 (0)	25 (11)	1.21 (1.27)	Slope-Foundation

		Translational	0 (0)	0 (0)	1.31 (1.35)	Slope-Foundation

5 Field Observations

As part of the observational method, an interpretation of the observed displacements and conditions on site is presented next and is linked to the performed numeric stability analysis in the preceding chapter.

5.1 Field Observations

No cracks or sudden displacements have been observed on the dump surface in the vicinity of the analyzed cross section, and the dump does not show any signs of instability.

SRK conducted a review of displacement measurements, both vertical and horizontal, from monuments established in Zone 3 to Zone 7. Out of these measurements, monuments in Zone 3-1 and Zone 3-2 represent the longest and most continuous displacement data set. SRK believes these to be representative of the settlement conditions of the entire WRD due to the consolidation (dissipation of excess pore water pressure) of the fine-grained soil in the foundation. Settlement curves for monuments in Zones 3-1 and 3-2 are shown in Figure 13.

The time required to achieve 90% of consolidation (i.e. almost complete dissipation of pore pressure induced by the dump construction) was estimated from the interpretation of settlement curves, using Taylor's method (Taylor 1948). Several factors impact the time of consolidation, like local soil conditions, the geometry of the fine-grained soil layer, real applied stress, and measurement accuracy. The calculated time varies between a minimum of about 5 days and a maximum of about 90 days (Figure 14). The conservative estimate of the time required to achieve a consolidation degree of 80% from the current condition is about 60 days.

5.2 Current Dump Geometry

The last dump advancement at the studied cross section was completed about 60 days ago, and a consolidation degree of about 80% was achieved based on displacement measurements (Figure 14). The fine-grained soils can be considered practically consolidated under the dump load for the determined consolidation state.

Since the fine-grained soil is consolidated (i.e., excess pore water pressure has already dissipated) and no load is applied to the dump surface or in the foundation near to the toe of the submerged dump, stability analysis of the current condition should be performed with shear strength parameters for drained loading conditions and hydrostatic water level. However, results of stability analysis of current dump configuration (Table 3) under drained loading conditions do not meet the minimum FoS specified in the guidelines (BCMWRP 1991) for some distance from the crest.

While field observations confirm a stable dump in the current conditions, calculations predict a dump failure with slide surfaces outcropping at some distance from the crest. To remove the inconsistency between observation and calculations, the factors involved in the stability calculations (mainly shear strength parameters of the waste rock and fine-grained soil for drained load conditions, and thickness and slope of the fine-grained soil layer) may be adjusted or

determined more precisely. However, SRK intentionally presented the stability analysis results in Table 3 without any adjustment of the factors involved in the stability analysis so as not to influence the outcome based on numerical manipulation.

For the current condition, setback distances of 22 m and 40 m were determined to get a FoS greater than 1.1 and 1.3 respectively (Table 3). Results from sensitivity analysis show that an increase in the shear strength of the clay of around 13% leads to a reduction of the setback distances between 40% to 20%, and an increase in the minimum factor of safety by 10% approximately. An increase in shear strength of that range is entirely plausible and therefore it illustrates the conservatism in the numerical analysis when compared to observations of the dump performance.

It is important to note that setback distances as calculated is based on the outermost leading edge of the dump. In reality, most of the dump is constructed using the stacker, and therefore the actual working surface is normally at least 22 m away from the outer crest as illustrated in Figure 15.

5.3 Dump Expansion

Based on the stability analysis for drained loading condition, a setback of 12 m is required for an intermediate dump configuration with a dump advancement into the lake of 42 m beyond the current extent.

In general, the stability analysis shows that the setback distances associated with FoS below 1.1 decreases as the dump advances towards the lake. No set back is required for intermediate stages with dump crests over 84 m from the current condition. Also, the minimum FoS increases above 1.1 as the dump construction progresses. The increase of the minimum FoS can be explained mainly by the decrease in the inclination (i.e. the geometry) of the fine-grained layer in the foundation.

Under these conditions, and based on the results included in Table 3, the calculated operational setback distance (i.e. FoS > 1.1) is 12 m for the 42 m crest advancement, and 0 m for the 84 m and 162 m advancements. Results from the sensitivity analysis on clay strength parameters indicates a reduction on the setback distance to 0 m, for the 42 m crest advancement, and an increase in the minimum FoS by 10%.

Also, the setback distance for permanent structures and stockpiles (i.e. FoS > 1.3) is 33 m for the 42 m crest advancement, 25 m for the 84 m advancement, and 4 m for the 162 m advancement. Results from the sensitivity analysis on clay strength parameters reduce these setback distances between 30% to 50%. The minimum FoS increases, in general, by 10%, except for the “Shallow Slope” failure type, because these slip surfaces do not include the foundation.

5.4 Seismic Loading

Under seismic loading undrained conditions would be experienced, and as can be seen from the results in Table 3, much of the WRD, especially under current conditions would have a FoS

below 1. Therefore, to ensure safety of personnel, the OMS Manual and SOP needs to be updated with clear protocols for evacuation of the WRD area when seismic events are identified.

5.5 Summary of Findings

To overcome the difference between observations and calculation results, the following design principles should be adopted as best practice for ongoing WRD construction:

- The fined-grained foundation materials behave in a drained manner when sufficient pre-loading time has occurred (i.e. drained shear strength parameters should be used to do the stability calculations);
- The operational setback distance at the crest is defined with a FoS > 1.1 (BCMWRP recommends a minimum FoS between 1.1 to 1.3 for short-term analysis of deep-seated failures); and
- The setback distance for permanent structures and stockpiles is defined to get a FoS > 1.30 (BCMWRP recommends a minimum FoS of 1.3 for long-term analysis of deep-seated failures).

The operational setback distance should be interpreted as the definition of a high-risk zone as currently identified in the SOP as follows:

- The zone should be clearly marked on site;
- No person shall work alone within this zone; and
- A clear, unobstructed escape route for the equipment working within this zone must always be present.

The setback distance for permanent structures and stockpiles defines a zone at the crest of the WRD where no permanent structures or stockpiles can be placed.

The numeric stability analysis results as presented clearly demonstrate that there remains a safety reserve with the drained shear strength parameters based on the comparison with the real WRD stability in the current condition. The maximum operational calculated setback distance (i.e. required to get a FoS above 1.1) for the current condition is 22 m at the most critical section. Future WRD configuration required less set back. However, a minimum operational setback distance of 10 m is recommended at all times.

The setback distance for permanent structures and stockpiles (i.e. required to get a FoS above 1.3) was estimated at 40 m. This set back is required for the current condition. Future WRD configuration requires less set back.

The sensitivity analysis performed on the shear strength of the clay (i.e. an increase of about 13% in shear strength) showed a reduction in setback distances between 20% to 50%, and an increase in the minimum FoS of 10% approximately. The selected increased shear strength of the clay is in the range of expected shear strength for this type of material, based on engineering judgment. Note that the increased shear strength still retains some reserve since it would be excepted that the entire foundation is not made of uniform soft clay.

6 Dumping Procedures and QPOs

This chapter provides an operational summary of subaqueous waste rock deposition at the Brucejack Gold Mine. Pretivm's engineering team manages the day-to-day waste rock deposition, and follow-up monitoring and surveillance following procedures outlined in the OMS Manual. The OMS Manual has been developed in accordance with SRK's design recommendations and undergoes updates as necessary. SRK is the EOR for the WRD.

Specifically, waste rock deposition is governed by the standard operating procedure (Brucejack Lake Waste Rock Disposal, SOP 011), which is an Appendix to the OMS Manual. All employees working on the WRD are provided training on this SOP.

6.1 Summary of Waste Rock Dump Surveillance Procedures

Table 4 summarizes the surveillance procedures used for managing the WRD.

Table 4: Summary of Waste Rock Deposition Surveillance Procedures

Inspection	Frequency	Critical Observation
Stability Analysis	• Start of every new deposition area.	• Determine anticipated settlement of new crest advance. • Assess FoS of new crest advance. • Assess preloading time for new crest advance to achieve acceptable factor of safety.
Settlement Surveys	• Immediately upon the completion of a 3 m crest advance. • Frequency afterwards based on-site Geotechnical Engineers requirements.	• Capture the baseline crest elevation for comparison with subsequent settlement surveying. • Conduct ongoing settlement surveying until necessary settlement has been achieved.

Geotechnical Engineer's Inspections	• At the start of every shift
	• After each break
	• At least every 4 hours if no breaks have occurred
	• At the start of a new work area
	• After every blast near the WRD
		• Inspect for signs of instability such as:
		  • Cracking
		  • Settlement
		  • Slope movement
		  • Changes in material type and moisture content
		  • Surface deflection from equipment
		• Inspect for delineators that mark the dump zones and restricted areas, and for proximity of safety equipment.
		• Inspect for safety equipment and personal protective equipment (PPE) worn by operators.

Equipment Operators Inspection	• At the start of each shift and continually during normal WRD operations	• Inspect for signs of instability on working surface and WRD face. • Be aware of equipment position, locations of egress points, and visibility. • Be aware of location of delineator cones, overhead lighting, and settlement monuments.
Health and Safety Audits	• Weekly	• Assess availability and use of safety supplies and PPE. • Assess adherence to deposition plan and SOP.

Inspection	Frequency	Critical Observation
		• Develop suggestions to improve WRD conditions and safety.
Engineer-of-Record Audits	• As deemed by the EOR	• Assess the deposition planning, tracking, and documentation being carried out on-site. • Determine if procedures are being followed and if WRD is being operated and is performing as designed.

6.2 Summary of Quantifiable Performance Objectives

QPOs were developed to manage the stability of the WRD. Table 5 summarizes the QPOs and their foundational methodology, responsible authority for their management, frequency of performance monitoring, and mitigation actions.

Table 5: Quantifiable Performance Objectives for Waste Rock Dump Construction

Description	QPO	Methodology	Responsibility	Frequency	Mitigation Actions
Waste Rock Dump Exposure	• Potentially acid generating (PAG) waste rock is to be subaqueously deposited below 1.0 m of water cover (1363.5 masl) within a 2 year (24 month) allowable exposure period.	• Excavate exposed PAG waste rock to an elevation of greater than 1.0 m below the Brucejack Lake level of 1364.5 m. • This excavation results in a minimum of 1.0 m of water cover over PAG waste rock. All excavations are to be guarded by a 1 m tall and 3 m wide safety berm that is set back 3 m from the excavation. • Where needed, a trafficking layer of non-acid generating waste rock is placed over the excavated PAG waste rock. • Elevations are confirmed by engineering staff and recorded in a digital database.	• On-site Geotechnical Engineers with support from Environmental Superintendent and Coordinator under the guidance of the Environmental Manager	• Actions to complete QPOs are ongoing and a component of operations work. • Due to weather constraints, the majority of the PAG waste rock excavation occurs in the summer months.	• The on-site Geotechnical Engineers with the support of the surface operations team will prioritize the location of PAG waste rock excavation and develop construction schedules and survey records.
Waste Rock Dump Preloading Time and Settlement Rate	• Experiential and judgement-based determination based on results of settlement surveys. Results must show that settlement rates are less than 0.03 m/day over two consecutive days.	• Foundation characteristics, depth of the lake and height of the waste rock continuously vary and therefore, settlement rate and magnitude are variable. • Preloading times are therefore also variable and cannot be prescribed.	• On-site Geotechnical Engineers with support from EOR as necessary	• Ongoing daily review of settlement survey results. • EOR formally reviews database bi-annually.	• Continue monitoring until the threshold values are reached.

Waste Rock Dump Stability	• Geodetic surveys are required a minimum of two times per day on all settlement monuments. Surveying frequency and timing must include:
	  • Initial survey immediately after the preloading material is constructed to establish a baseline.
	  • An initial check survey within 6 to 12 hours of the baseline survey.
	  • Subsequent surveys at 12-hour intervals until the Geotechnical Engineer specifies otherwise.
		• The Geotechnical Engineer reviews settlement results and applies experiential judgement to determine when preloading has been completed and when it is safe to deposit more waste rock.
		• As necessary, the Geotechnical Engineer will conduct numerical modeling, stability analysis and settlement analysis to confirm his experiential judgement.
			• On-site Geotechnical Engineers with support from EOR as necessary	• Ongoing daily review of settlement survey results.
				• Ongoing daily review of WRD stability though numerical modeling, stability analysis and settlement analysis as necessary.
				• Visual assessment of WRD stability every 4 hours.
				• EOR formally reviews database bi-annually.
					• The Geotechnical Engineer and the Manager Technical services must be contacted if the survey frequency cannot be completed to determine an action plan.
					• The Geotechnical Engineer must track the date when the survey(s) were attempted and report on the daily reports when future surveys will be attempted.

Waste Rock Dump Inspections	• Site inspections to visually assess the stability of active and inactive deposition zones.
	• Site inspections are required to be documented.
	• Inspections can also include the observations of the equipment operators and supervisors.
		• Sloughing and slope movement (including from equipment traffic) is expected and considered normal, however, within the constraints identified in the design reports and the conditions set here:
		  • Visual inspections focussing on surface cracks or other signs of instability within the preloading area.
		  • Cracks which form within the safety berm or on the dump surface must result in the stoppage of work (including egress of workers and equipment from the area) until an assessment by the engineer is completed.
		  • A change in deflection magnitude resulting from equipment traffic must be addressed by the engineer.
			• On-site Geotechnical Engineers with support from EOR as necessary	• Visual assessment of WRD stability every 4 hours.
				• EOR formally reviews database bi-annually.
					• Cracks forming in the preloading berm are immediately communicated to the Geotechnical Engineer. They are photo documented in the daily reports and visually assessed during regular inspections.
					• Cracks/slumps forming in the safety berm or in the dump pad surface result in an immediate work stoppage on the entire dumpsite. All signs of instability are immediately communicated to the Geotechnical Engineer and the EOR and recorded in the daily reports.

Rate of Waste Rock Dump Construction and Crest Advance	• The upper limit of waste rock deposition is 75,000 m^3/week (10,715 m^3/day) provided that preloading settlement rates meet expectations. • During normal operations between 600 and 1,000 m^3/day of waste rock will be supplied to the waste dump from the underground mine, which is less than the upper limit. • The Geotechnical Engineer prescribes the deposition zones that have met the preloading requirements in the daily deposition plan.	• The rate of waste rock deposition is related to the rate that the crest advances during the preloading process. • The rate that the preloading is advanced is operationally limited to the reach of the hydraulic excavators and conveyor system (stacker) used to bail waste rock over the preloading zone and the preloading time discussed above. • Typically, the preloading zones are 6 m wide and the current equipment has an approximate reach of 12 m. With the excavator situated behind the 6 m wide preloading area the effective reach of waste rock placement is 6 m into the lake and therefore, the rate of waste rock crest advance is 6 m per preloading cycle.	• On-site Geotechnical Engineers with support from EOR as necessary	• Ongoing daily activity.	• Rate of WRD construction is determined by the rate of construction of the preloading berms and by rate of settlement during preloading in the lake bottom sediments – it cannot be a fixed value. • To decrease the rate of WRD construction, decrease the capacity of the equipment used to construct the preloading berm. • To increase the rate of WRD construction, increase the capacity of the equipment used to construct the preloading berms. However, the rate of WRD construction will be limited to the availability of rock and the time required to meet the preloading requirements.

6.3 Summary of Waste Rock Deposition Methods

6.3.1 Screening and Stacker Deposition (8-inch Minus Material)

Underground waste rock is screened using a vibrating shaker deck to separate 8-inch and larger rock that would damage the rubber conveyor belts. Screened 8-inch and smaller (minus) rock is conveyed into the lake using a stacker.

The dumping procedure using the stacker is presented in Figure 16. Step 1 entails positioning the stacker with its wheels and rig mat pads as illustrated in Figure 16. The purpose is to distance the point load of the stacker as far back as practical from the WRD crest until a buttress of waste rock (shown in pink) is deposited along the toe and face of the dump. Step 2 entails infilling the gap between the outer cone and the previous crest, before advancing the stacker. Step 3 entails establishing a new preloading monitoring station, and after the required settlement QPOs have been attained the stacker is advanced to repeat the process (Step 4).

6.3.2 Excavator Deposition (8-inch Plus Material)

Separated 8-inch and greater (plus) waste rock is conventionally deposited into Brucejack Lake using a hydraulic excavator assisted by a tracked dozer as illustrated in Figure 17. 8-inch plus rock is dumped a minimum of 10 m away from the excavator to maintain a safe working area as illustrated by Step 1 in Figure 17. Step 2 entails end dumping material outside of the safe zone. Step 3 entails use of a small dozer to push the stockpiles into the safe zone to allow the excavator to reach it. Step 4 entails completion of the preloading section and installation of the monitoring instrumentation. At all times a tracked dozer advances the waste rock to the excavator on the right-hand side of the equipment to maintain a clear egress path for the equipment operator. Equipment operators are in constant communication with one another.

7 Closing Comments

Pretivm is proposing to increase overall life-of-mine ore production of the Brucejack Gold Mine from 16.5 Mt to 18.5 Mt, which will result in increased tailings and waste rock deposition in Brucejack Lake. Pretivm is also seeking approval for the flexibility to maximize waste rock deposition to either Brucejack Lake or to secondary stopes in the underground mine. The higher overall ore production and/or maximizing waste rock deposition to the lake will result in an expanded surface footprint of the WRD, and a thicker subaqueous tailings deposit. Subsequently the waste rock may extend onto unconsolidated tailings.

Although the original design analysis for the Brucejack WRD (SRK 2014) did not consider deposition on tailings, characterization data confirm that tailings will have greater strength than some of the weaker clays analysed as a foundation material (SRK 2015a). Ongoing WRD construction for the last 2 years, including back-analysis of three dump failure incidents (SRK 2015b, 2016b, c), has confirmed that the original design was robust and remains appropriate. Notwithstanding this, additional numerical analysis was completed and correlated with observational data, which confirmed that the dump construction can be executed safely, provided the conditions stipulated in the OMS Manual and SOP are maintained.

The updated design as presented in this report has confirmed that the existing dumping SOP (SRK 2017, Appendix A-1) and QPOs as defined in the current OMS Manual (SRK 2017) remain valid and relevant to ensure safe dumping in Brucejack Lake. This dumping SOP is independent of sediment type or thickness as it is based on the fundamental understanding that the foundation of the dump cannot initially carry the load.

SRK, as the EOR is therefore satisfied that the proposed mine expansion and implementation of either the Scenario 1 or 2 waste dumping scenarios (or anything in-between) does not require any changes to the WRD design analysis, dumping SOP or QPOs at this time, and that following of the already established protocols will ensure ongoing safe dumping.

BRUCEJACK MINE

Appendix 4-1
Reclamation and Closure Plan

March 2023

VERSION CONTROL

Revision #	Date Released	Revisions
1	May 2015	Initial issuance.
2	2018	Updated to reflect constructed infrastructure rather than proposed, and to separate infrastructure within the M-243 permitted area from ancillary infrastructure located outside of that area.
3	2020	Updated as Chapter 3 of the 2020 Mine Plan and Reclamation Program Update, including to address content requirements of *Mines Act* Permit M-243 Condition E.14.
4	2023	Updated areas of disturbance and figures to include infrastructure changes and updated PMA since 2020 (Amendment #8, approved November 2022), Five Year Mine Reclamation Plan to reflect closure in 2029, addition of east WRD and associated infrastructure, reclamation research program progress; and changes to closure approaches such as increased commitment to remove some types of waste materials. New content added to address EMLI information requirements (ecohydrological modeling considerations; landforms and drainage pre-mine, during operations, and post-mine; temporary closure content; and climate change).

ACKNOWLEDGEMENTS

The Brucejack Mine Reclamation and Closure Plan was originally prepared pre-mine for Pretium Resources Inc. by ERM as chapter 5 of the 2015 Applications for *Mines Act* and *Environmental Management Act* Permits (Pretium 2015). The plan was subsequently revised by Pretium Resources Inc. (Pretium) to reflect updates from construction and operations and to make it specific to the M-243 permitted area. Sylvia Van Zalingen, M.S., P.Ag. (Pretium Resources Inc.), has prepared sections 1, 2.1, 2.3, 3.2, 3.3, 3.4, 3.5, 3.6.1, 3.6.2, 5, 6, 7, 8, 9, 10, 11, 12.1, 12.6 and 12.7 of this updated Brucejack Mine Reclamation and Closure Plan. Justin Straker, M.Sc., P.Ag. (Integral Ecology Group (IEG)) has prepared the ecohydrological modeling discussion in section 2.2, and sections 3.1, 3.6.3, 3.7 and 4, including information on the mine's reclamation research program that is being lead by IEG. Jessica Lowey, M.Sc., P.Ag. (ERM) has prepared or approved soils and vegetation content in sections 2.2 (paragraphs 3 to 6) and 2.3 (paragraphs 2 and 4), and has prepared section 3.2 Climate Change Considerations. Wade Brunham, M.Sc., R.P.Bio. (ERM) has prepared or approved wildlife content within sections 2.2 (paragraphs 3 to 6) and 2.3 (paragraphs 2 and 4). Robert Goldblatt, B.Sc., R.P.Bio. has prepared Section 12.2. Laura Findlater, B.Sc., P.Geo. has prepared Section 12.3. Dinesh Devathasan, B.A.Sc., P.Eng. has prepared Sections 12.4 and 12.5.

LIST OF ACRONYMS AND ABBREVIATIONS

Terminology used in this document is defined where it is first used in each chapter. The following list will assist readers who may choose to review only portions of the document.

ATV	All terrain vehicle
BC	British Columbia
BEC	Biogeoclimatic Ecosystem Classification
BJAR	Brucejack access road
CCME	Canadian Council of Ministers of the Environment
CMAun	Coastal Mountain-heather Alpine
CODE	Health, Safety and Reclamation Code for Mines in British Columbia (2022)
CSR	Contaminated Sites Regulation
CWP	Contact water pond
DPS	Diesel power station
EMA	BC *Environmental Management Act*
EMLI	Ministry of Energy, Mines and Low Carbon Innovation
HDPE	High-density polyethylene
ICP-MS	Inductively coupled plasma mass spectrometry
Knipple camp	Camp located at BJAR km 56, serving the Knipple transfer area and BJAR to km 71
Knipple transfer area	BJAR support area, including for transfer of supplies, equipment and personnel on and off the Knipple Glacier
Lakeshore Drive	BJAR km 71-73.3 (segment extending between the top of the Knipple Glacier (km 71) and the mine site (km 73.3)
LOO	Licence of Occupation
MA	BC *Mines Act*
M-243	BC *Mines Act* Permit M-243

masl	Meters above sea level
MECCS	BC Ministry of Environment and Climate Change Strategy
MEMPR	BC Ministry of Energy, Mines and Petroleum Resources
Mine Site	Core mine infrastructure area at the southwest end of WRTSF
Mine Site Area	Mine infrastructure west of upper Knipple Glacier (km 71.6), including the NPAG quarry, upper BJAR, and the mine site
ML/ARD	Metal leaching/acid rock drainage
Newhawk	Newhawk Gold Mines Ltd.
NP	Neutralization potential
NPAG	Non-potentially acid generating
NPK	Nitrogen, phosphorus and potassium
OMS	Operations, maintenance and surveillance
PA-107025	BC *Environmental Management Act* Air Permit 107025
P.Ag.	Professional Agrologist
PAG	Potentially acid generating
PE-107835	BC *Environmental Management Act* Effluent Permit 107835
PMA	Permitted mine area
Pretium	Pretium Resources Inc.
ROW	Right-of-way
RTV	Rugged terrain vehicle
SFE	Shake flask extraction
SOP	Standard operating procedure
STP	Sewage treatment plant
tpd	tonnes per day
TSS	Total suspended solids

UG	Underground
VOK	Valley of the Kings
Wildfire camp	Camp located at BJAR km 1, supporting Wildfire security and BJAR transport and operations
Wildfire security	Security gate and screening located at BJAR km 1
WRD	Waste rock dump
WRTSF	Waste rock and tailing storage facility
WT	Water treatment
WTP	Water treatment plant
WZ	West Zone

1 INTRODUCTION

This is the updated Reclamation and Closure Plan for the Brucejack Mine, originally presented as the Brucejack Reclamation and Closure Plan in the 2015 Brucejack Gold Mine Project Application for *Mines Act* and *Environmental Management Act* Permits (*MA & EMA* Permits) (Pretium 2015). It incorporates reclamation program information included in Annual Reports for *Mines Act* Permit M-243 (M-243), *Environmental Management Act* Effluent Permit 107835 (PE-107835), and Air Permit 107025 (PA-107025) (Pretium 2016, 2017, 2018, 2019, 2020a, 2021, and 2022a). Content includes end land use and capability objectives; reclamation approaches, prescriptions and research; reclamation planning for the next five years and at closure; and planned post-closure monitoring.

Brucejack Mine reclamation and closure planning has been integrated with mine planning and design since pre-construction environmental assessment and related pre-construction design work began in 2012 and 2013. The mine and its operations have been planned and designed to minimize the terrestrial development footprint and to prevent significant adverse effects on the downstream aquatic receiving environment, including both water quality and aquatic biota.

Based on the current mine plan [refer to 4950 tpd Joint M-243/PE-107835 Amendments Application (Pretium 2022b, Chapter 3)], the remaining mine life is approximately 7 years, with operations ceasing at the end of 2029. This will be followed by a closure phase estimated at three years that includes two years of closure and reclamation within the M-243 area, and a third year of reclaiming off-site mine related infrastructure [i.e., the Brucejack Access Road (BJAR) and adjacent infrastructure below Knipple Glacier and extending to the Highway 37 intersection, and the Statutory Right-of-Way (ROW) authorized portion of the transmission line]. A post-closure monitoring period of ten years is planned for the M-243 area following mine closure.

This updated Reclamation and Closure Plan addresses mine infrastructure components and site disturbance authorized under M-243, including mine development within the Permitted Mine Area (PMA) portion of the mining leases (Figure 1-1) and the portion of the mine's transmission line extending south from the mining leases to Pretium's Mineral Claim #1026976 (Figure 1-2). Permit M-243 authorizes the northernmost 19.5 km of the transmission line, whereas the 37.5 km segment located south of that is authorized under Statutory ROW #6408729.

Brucejack Mine surface disturbance areas are limited in extent due primarily to it being an underground mine. The M-243 approved PMA is 659.3 ha (Figure 1-1 and Figure 1-2), with approximately 195 ha covering a 100 m corridor along the northernmost 19.5 km of the transmission line, and the remaining approximately 464 ha being located within the mining leases. Actual disturbance at end of 2022 was calculated at 278 ha (terrestrial disturbance area total for mine site 55 ha, buffer from historical exploration 66 ha, transmission line 66 ha, Waste Rock and Tailings Storage Facility (WRTSF) and Waste Rock Platform 76 ha, and km 72 Non- Potentially Acid Generating (NPAG) quarry 14 ha), however the historical exploration buffer areas are minimally disturbed and have been partially reclaimed. The terrestrial disturbance area total for the mine site primary infrastructure area is 55 ha [lower and upper camps 5 ha, plant site 38 ha, pond 0.02 ha, roads 11 ha, overburden stockpile 0.4 ha, Contact Water Pond (CWP) 0.7 ha], which includes mine site infrastructure and related disturbance areas. The transmission line calculated surface disturbance is primarily within the 6.7 km southernmost segment that is below treeline. Most of the northernmost 12.8 km of the transmission line is comprised of clear spans over bedrock and ice; towers in this section are anchored in bedrock.

Figure 1-1. *Mines Act* Permit M-243 Permitted Mine Area Boundary within Mining Leases

Figure 1-2. *Mines Act* Permit M-243 Permitted Mine Area Boundary

Tree and shrub clearing within the M-243 portion of the transmission line right-of-way during construction was necessary for only the southern 6.7 km forested section, and mainly occurred to widths between 58 and 66 m. Access was almost entirely by helicopter, and trees were hand-felled and left in place with no disturbance of surficial soils and limited disturbance of existing vegetation over most of the cleared area. The tree felling approach was planned and approved, in part as an environmental protection/mitigation measure to limit ground-based access along the cleared ROW. Disturbance of surficial materials was limited, being primarily confined to tower bases. The tower sites were seeded with Pretium's native species seed mixes following completion of construction at each site. Post-construction, vegetation along the transmission line has continued to grow, undisturbed. Some mechanical vegetation control may be necessary in future if/when woody vegetation cover reaches heights that pose a safety and operational risk for the line.

2 END LAND USE AND CAPABILITY OBJECTIVES

2.1 BACKGROUND

End land use and capability objectives for Brucejack Mine components have been integrated with mine planning and design to promote successful reclamation and closure. Pre-development land use and conditions generally form the basis for identifying the end land use and capability objectives. The requirement to consider end land use for the mine site area is stated in Section 10.7.4 (Land Use) of the Health, Safety and Reclamation Code for Mines in British Columbia (Code) (EMLI 2022): "The land surface shall be reclaimed to an end land use approved by the chief permitting officer that considers previous and potential uses." The requirement to achieve an appropriate post-mine land capability is stated in Code Section 10.7.5 (Capability): "Excluding lands that are not to be reclaimed, the average land capability to be achieved on the remaining lands shall not be less than the average that existed prior to mining, unless the land capability is not consistent with the approved end land use or compromises long-term physical and/or geochemical stability."

These Code requirements are reflected in M-243. Condition E.3 requires Pretium to "reclaim the land with the intent of re-establishing average pre-mining capability to the following end land use objective: wildlife habitat, particularly matrix habitat for mountain goat, grizzly bear and hoary marmot on the mine site and high elevation sections of the transmission line, and moose and grizzly bear habitat at lower elevations of the transmission line. Achieving land capability objectives and habitat enhancement shall guide the reclamation program." Part E of M-243 contains additional reclamation related requirements.

This updated Reclamation and Closure Plan provides the plan of how end land use and land capability objectives will be achieved to the extent feasible, or site conditions created that will allow these to be achieved, by the end of the Brucejack Mine's closure period.

2.2 MINE SITE AREA

The Brucejack Mine site area encompasses all existing and proposed infrastructure within the mining leases, which are located west of the upper Knipple Glacier. Infrastructure in this area includes the underground mine and associated surface processing plant (mill) with Water Treatment Plant (WTP), camp, maintenance shop, water management infrastructure, WRTSF, BJAR ~km 71 to km 73.3, and the km 72 NPAG quarry (Figure 2.2-1). The mine is situated in rugged mountainous terrain at approximately 1,400 meters above sea level (masl). Surrounding peaks reach elevations exceeding 2,300 masl. Glaciers and ice fields surround the mine site area to the west, south and east. Recent and rapid deglaciation has resulted in over-steepened and unstable slopes in many locations. Recently deglaciated areas typically have limited, if any, soil development; where present, soils are derived from glacial till and colluvium.

The mine's primary surface infrastructure area is located along the southwest shore of the WRTSF in an area dominated by gossanous (mineralized materials to surface) bedrock outcropping with some slightly weathered parent materials occurring as pockets with alpine vegetation (Figure 2.2-1).

Prior to mine construction, the Brucejack Mine area was characterized as dominantly exposed bedrock, with approximately 80% of the mine site described as non-vegetated or sparsely vegetated

(Figure 2.2-2), with underlying limited extent and poor quality of soils (ERM Rescan 2014). The mine site area is located above the tree line in the Coastal Mountain-heather Alpine (undifferentiated; CMAun) Biogeoclimatic Ecosystem Classification (BEC) zone. This zone has the harshest climate of any biogeoclimatic zone in British Columbia (BC). Temperatures are low for most of the year, with much wind and snow. Temperatures remain low even during the growing season, which has an exceptionally short frost-free period. Mean annual temperatures range from 0°C to 4°C. Patches of snow, névé, and firn persist late into the year.

Figure 2.2-1. Brucejack Advanced Exploration 2013, Showing Mine Site Bedrock Outcrops and Pockets of Weathered Parent Materials.

Figure 2.2-2. Brucejack Mine Site 2012, Showing Bedrock Exposures and Limited Vegetation Extent.

Vegetation community development within the mine site and its vicinity was limited by the poor quality and limited availability of growth media, high snow pack, high winds and low temperatures. Vegetation classes of the Alpine Group (MacKenzie 2012) were present as a mosaic across the landscape, the distribution of which was determined by growth media depth, drainage and microclimate. The vegetation includes small shrubs, lichen and mosses. Most of the ecosystems within the mine site area are early seral, disclimax, or edaphic climax ecosystems. Early seral ecosystems, such as the areas mapped as alder thicket, are those early in the successional status chrono-sequence. These include non- and sparsely vegetated, pioneer seral and young seral communities. Edaphic ecosystems include those maintained by local climatic and soil conditions that enable an ecosystem to perpetuate itself.

The small areas of vegetation that were present (and which remain in some locations) include small shrubs, lichens and mosses. Alpine Tundra Class vegetation communities are dominated by hardy ericaceous shrubs that can withstand the desiccating winds common in alpine environments. Alpine vegetation classes include Alpine Fellfield, Heath, and Meadow classes. Detailed vegetation and terrain mapping and descriptions of the mine site and vicinity are provided in Appendix 5 of the 2012-2013 Terrestrial Ecosystem Baseline Studies (ERM Rescan 2014).

Pre-mine habitat assessments of the mine site classified the habitat as matrix habitat for wildlife species resident in the general vicinity: hoary marmot, grizzly bear, and, to a more limited extent,

mountain goat (ERM Rescan 2013). Aerial and ground surveys in 2012 and 2022 found hoary marmot colonies northwest and west of the mine site, along and near Brucejack Creek. Beginning during Pretium's advanced exploration activities in 2011, grizzly and/or black bears have been occasionally observed passing through the area north of Brucejack Creek and the (now) WRTSF, or south and high above the mine site along the winter access that traverses the upper Valley of the Kings (VOK) area.

An additional consideration pertinent to end land use is that growth media (unconsolidated overburden and soils) at the mine site have naturally elevated metals concentrations, including arsenic, due to being located on gossanous material. Additional details are provided below in Section 3.2.

At closure, the mine site will be reclaimed to matrix habitat for mountain goat, grizzly bear, and hoary marmot to facilitate movement by these target species and others, into better habitats. This will be achieved by reclamation measures that result in terrain that is free of mine related obstacles or hazards, thereby allowing free movement through the area by wildlife. The post-closure mine site will have low vegetation cover, consistent with its pre-mine condition and with surrounding areas, as most of the adjacent landscape is comprised of unvegetated bedrock exposures.

It is not currently possible to conduct ecohydrological modelling for the mine site and to present related tabular and spatial comparisons of pre-development and post-closure land use capabilities, for two reasons:

1. The Brucejack Mine site occurs in the CMAun BEC zone, for which a finer-resolution classification of site series does not exist. Thus pre-development (baseline) mapping of the mine-site area shows only five general ecosystem classes, listed here in rough order of prevalence: alpine ecosystem, glacier/permanent snow, moraine, water, and exposed soil. Of the alpine ecosystem class, as noted above, most of its area is sparsely or non-vegetated, as can be seen in Figure 2.2-1 and Figure 2.2-2. A pre-development table and map of ecosystems and capability therefore provides limited resolution (refer to Figure 2.2-3).
2. Objectives of the current Brucejack Mine reclamation research program include addressing three fundamental questions and limitations to reclamation at the mine site, as discussed in Section 3.6:

    a. What is the potential for metal uptake in vegetation that establishes on mine site surficial materials;

    b. Does any metal uptake that occurs pose or have the potential to pose concerns for any wildlife consuming this vegetation; and

    c. Given the acid generating or potentially acid generating (PAG), and metalliferous characteristics of mine site surficial materials and their unsuitability on that basis as reclamation material, should there be active revegetation of the mine site as part of the mine reclamation program (i.e., revegetation that would result in vegetation cover beyond what occurs naturally; potentially increasing the risk beyond what would occur naturally).

Figure 2.2-3. Brucejack Mine Site Terrestrial Ecosystem Map

2.3 BRUCEJACK TRANSMISSION LINE

Brucejack transmission line infrastructure will be removed during final reclamation. Due to the transmission line surface disturbance being primarily limited to tower base sites and effects to vegetation cover consequently being very limited, vegetation cover will have essentially the same extent at closure as it did pre-construction.

The M-243 portion of the Brucejack transmission line grades from old forest in the south to early seral ecosystems and non-vegetated areas in the north. Within the southern 6.7 km forested segment, mountain hemlock (*Tsuga mertensiana*) is a dominant species, with lesser presence of western hemlock (*Tsuga heterophylla*). Other tree species include subalpine fir (*Abies lasiocarpa*), Engelmann spruce (*Picea engelmannii*) and black cottonwood (*Populus trichocarpa*). Colluvium, moraine, rock, and ice are the dominant surficial materials mapped in the northernmost 12.8 km of the transmission line (ERM Rescan 2014).

As above, most of the M-243 portion of the transmission line route is located either above treeline or in high subalpine areas. Transmission line construction was helicopter supported, with road-based support within the M-243 section limited to a few towers near the BJAR. Transmission line tower base sizes vary with the tower type, with most being approximately 3 m in diameter. Towers were sited on bedrock as much as possible (Figure 2.3-1). Due to all of these factors, surface disturbance and effects on vegetation as a result of the transmission line are very limited.

At closure, the transmission line will be reclaimed to wildlife habitat, particularly matrix habitat for mountain goat, grizzly bear and hoary marmot in the high elevation sections, and moose and grizzly bear habitat at lower elevations of the transmission line. Transmission line development has not altered terrain except to a very limited extent (approximately 200 m length) at Knipple transfer area. Removal of the towers, conductors and Knipple substation will remove whatever limited obstacles to wildlife movement are posed by the transmission line. Due to the lack of soil disturbance between tower sites in the southern vegetated portion of the M-243 transmission line extent, the limited extent of tower sites on materials other than bedrock, and because where present, disturbed soils around tower bases have already been seeded, the end land use objectives for the transmission line are expected to be achieved.

Figure 2.3-1. Transmission Tower on Bedrock in M-243 Vegetated Section (Photo August 2019).

3 RECLAMATION APPROACHES

3.1 BACKGROUND

The Brucejack Mine site area has multiple unique or unusual characteristics that present substantial challenges for vegetation establishment and are not typical of mines in BC. As discussed above, these characteristics include the high elevation and harsh climatic conditions of the mine site area, the ubiquity of geochemically reactive gossanous materials throughout the mine site, and the pre-mine lack of soils and ecosystem development.

Because of these challenges, the general approach to reclamation planning for the mine has been to minimize surface disturbance through mine design and construction, and to then create post-mine topography and conditions that will achieve the matrix habitat end land use and support passive natural revegetation to the extent feasible. Key reclamation methods include recontouring to prevent barriers to movement of the target wildlife species and to create stable drainage features, and decompaction/scarification of potential growth media. Some limited additional measures are being investigated as a component of the reclamation research program, discussed below.

The following sections describe pre-development conditions and the approach to surficial materials use for reclamation within the Brucejack Mine site area and the M-243 portion of the transmission line. A key issue informing this approach is that overburden available as growth media within the mine site is predominantly PAG, with elevated element concentrations, particularly arsenic (Shaw and Simpson 2016) (Pretium 2020b, Appendix 3.3-1). This overburden is presently considered not suitable for use in reclamation and is instead recommended for handling in ways that will minimize potential for incremental acid rock drainage and metal leaching. It is not presently known if there are any areas within the mine site in which surficial materials may be amenable to revegetation – this question is being investigated as part of reclamation research described in 2020 Mine Plan and Reclamation Program Update (Pretium 2020b) and initiated in 2021.

Until the reclamation research program is sufficiently advanced to resolve active revegetation areas and methodologies, the reclamation plan and associated reclamation liability costing assume that mine site disturbances will generally be recontoured, de-compacted as feasible, seeded with the Brucejack high elevation native species seed mix, and fertilized (i.e. to supplement passive natural revegetation).

3.2 CLIMATE CHANGE CONSIDERATIONS

The BEC units across the province will inherently change as temperatures and precipitation amounts and types change into the future. The predictive changes in the BEC zones that overlap or are adjacent to the Project illustrate the effects associated with a predicted substantial raise in temperature and a predicted minor increase in precipitation amount, but a likely shift in precipitation type (BC Climate Explorer 2021). The lower elevation Mountain Hemlock (moist maritime parkland; MHmmp), with warmer mean annual temperatures, is predicted to begin replacing the higher elevation CMAun, which currently has much lower mean annual temperatures. These two ecosystems are predicted to overlap within 60 to 80 years (BC Climate Explorer 2021). The predicted differences in mean annual temperature and precipitation between the Engelmann Spruce - Subalpine Fir (undifferentiated parkland; ESSFunp) and the higher elevation Boreal Altai Fescue Alpine (undifferentiated parkland; BAFAun), are considerably less even now; thus, resulting in the possible replacement of the ESSFunp into higher elevations over time.

An understanding of climate change predictions and the associated effects on local ecosystems is intended to allow for the adaptation of final reclamation prescriptions to suit the current and predicted local climate.

3.3 SURFICIAL MATERIALS

3.3.1 Brucejack Mine Site Area

The Brucejack Mine site area is located in the high elevation, very cold CMAun BEC subzone. Prior to mine construction, vegetation was sparse, generally covering less than 20 percent of the plant site and vicinity and with little to no cover at km 72 NPAG quarry (ERM Rescan 2014) (Figure 2.2-2 and Figure 3.2-1). This sparseness is due to the extensive occurrence of bedrock, and the limited amount and poor quality of unconsolidated surficial materials.

Baseline surveys of mine site surficial materials (ERM Rescan 2014) determined that most of these materials are insufficiently weathered and developed to meet the definition of soils. Where soils are present, they are generally of poor quality for revegetation due to their high coarse fragment content, lack of development, and/or shallow depth to bedrock. Laboratory analyses indicate that most mine site surficial materials have metal exceedances based on Canadian Council of Ministers of the Environment (CCME) soil quality guidelines; these exceedances include arsenic (ERM Rescan 2014).

A thorough assessment of mine site overburden geochemical characteristics and suitability for use in reclamation was conducted in 2015 (Pretium 2020b, Appendix 3.3-1). This assessment indicated that mine site overburden is predominantly PAG. All overburden samples exceeded the CCME Industrial Soil Quality Guidelines for arsenic. The surficial materials characterization is consistent with the mine site's location in/on a gossan (mineralized, oxidized rock extending to surface; Figure 3.2-2).

In synthesis, the survey data indicate that soils and other surficial materials at the Brucejack Mine site are not suitable for use as reclamation growth media, and that overburden should not be spread as a reclamation cover but should be treated in a manner to minimize generation of acid rock drainage (Shaw and Simpson 2016). Although approximately 30,000 m^3 of this material was salvaged and stockpiled as required by the Ministry of Energy, Mines and Low Carbon Innovation (EMLI), there is currently no plan to use these materials as reclamation covers pending results from ongoing reclamation research. Amendment of these materials, such as attempting to add neutralizing compounds, is not a feasible option. Vegetation cover pre-mine was limited and implementing measures such as enhancing soil size materials to promote plant growth is currently considered to pose a risk to local wildlife in that it may attract wildlife to consume vegetation with potential to contain elevated metals concentrations.

Figure 3.2-1. Brucejack Mine Site 2008, Showing Sparse Vegetation Cover.

Shallow ripping will be conducted in areas of the mine site disturbance footprint as appropriate following decommissioning of structures to decompact surficial materials and facilitate any natural regeneration by native vegetation communities that may occur. These activities are consistent with the passive revegetation approach discussed below in Section 3.4.

Rock outcrops dominate the steep terrain at the km 72 NPAG quarry site and along the BJAR between the eastern boundary of the mining leases (~km 71) and the mine site (km 73.3). This section of the BJAR was pre-existing from prior exploration activities. It was widened and upgraded as required during mine construction to meet EMLI/Code safety requirements; this was primarily accomplished through placement of quarried NPAG rock from the km 72 NPAG quarry. No surficial materials salvage was feasible at these locations during mine construction. Shallow ripping will be conducted on the BJAR surface as feasible at closure, provided this does not compromise site stability and water management. The km 72 NPAG quarry will remain as exposed bedrock and boulders at closure.

Figure 3.2-2. Brucejack Mine Site Located On/In a Gossan (Photo August 2013).

3.3.2 Transmission Line

As described in Section 2.3, the northernmost 12.8 km of the Brucejack transmission line is comprised of clear spans over bedrock and ice dominated alpine terrain (Figure 3.2-4). Towers and lines were installed by helicopter. Towers are anchored in bedrock (Figure 3.2-3 and Figure 3.2-4). Reclamation of this section of the transmission line at closure will entail removal of towers and conductor line.

The southern 6.7 km of the M-243 transmission line section was mostly vegetated pre-construction, however even here there are extensive areas of bedrock exposure or shallow growth media over bedrock, and most towers in this section are also anchored in bedrock (Figure 2.3-1). Trees were hand felled, and soils and surficial materials were not disturbed except at the tower sites due to tower construction using helicopter support. The small, disturbed areas around tower sites with potential to support plant growth were seeded following transmission line construction. During mine closure, the towers and conductor along this portion of the transmission line will also be removed. No reclamation specific to surficial materials is planned at these tower sites at closure beyond minor recontouring, including covering concrete foundations to the extent feasible, and additional seeding as appropriate.

Figure 3.2-3. Transmission Line Tower, Northernmost Transmission Line Section (Photo July 2020).

Figure 3.2-4. Transmission Line Towers in Northernmost Bedrock and Ice Section (Photo July 2018).

3.4 LANDFORM DESIGN AND EROSION CONTROL

3.4.1 Mine Site Area

3.4.1.1 Pre-Mine Landforms and Drainage

The Brucejack Mine site is located in a bedrock controlled, high elevation area (Figure 3.3-5.). Pre-mine, and in remaining undisturbed or minimally disturbed areas, the bedrock surface was/is irregular with rounded surfaces broken by crevices and depressions where snow accumulates. There were localized areas with shallow, slightly weathered overburden and limited areas with developed soil cover. Most of what is now the mine site drained to Brucejack Lake (now the WRTSF), with some areas draining to Camp Creek or directly to Brucejack Creek (Figure 3.3-1 and Figure 3.3-2). Bedrock and shallow overburden extended to the lake shoreline, with few level areas.

Figure 3.3-1. Pre-mine sub-watersheds within the Brucejack Creek Watershed

Figure 3.3-2. Pre-Mine Drainage Areas

3.4.1.2 Operations Landforms, Water Management and Erosion Control

Mine construction required development of level pads (Figure 3.3-6 and Figure 8.1-1) for surface infrastructure such as the mill and lower camp buildings. Parts of the pads were created by bedrock excavation; the remainder of the leveling was achieved by filling and compaction using excavated crushed rock sourced from the km 72 NPAG quarry. The pads are designed to be stable and resulted in approximately 20 ha of level area being created on the site (see also Figure 8.1-1, pads only).

A contact water collection system was constructed to collect runoff from the mine site pads bedrock excavations as had been planned and permitted pre-mine because this bedrock is or is assumed PAG, and in accordance with the metal leaching and acid rock drainage (ML/ARD) requirements of M-243 and the Brucejack ML/ARD Management Plan (Pretium 2021, Appendix 3-1-1-6). The contact water collection system collects water from an area of approximately 7 ha that pre-mine drained to Camp Creek and re-directs it to the WRTSF (Brucejack Lake) via the water collection and treatment system. It also collects water from an area of approximately 12 ha that pre-mine drained to the outlet section of Brucejack Lake or to Brucejack Creek and re-directs it to the WRTSF (Brucejack Lake) via the water collection system.

The WRTSF is authorized for the sub-aqueous deposition of mine waste rock and tailings and effectively settles suspended sediment resulting from this deposition. The contact water collection system actively and passively directs surface runoff from within the contact water collection portion of the mine site (most of the mine surface infrastructure areas; Figure 3.3-3) to the CWP. Water in the CWP is pumped to the WTP located in the mill, where it is treated prior to discharge to the WRTSF. Therefore, suspended sediment from any erosion within the contact water collection area is directed through the CWP and the WTP. Mine infrastructure areas east of the contact water collection system, including the waste management and other facilities near the East (Johnson Creek) diversion channel, the km 72 NPAG quarry, and the BJAR section from approximately km 72 westward, all drain passively to the WRTSF.

The West Zone pad and portal area is located outside of the contact water collection area. The portal itself drains inward into the underground mine. Water within the underground mine is collected and pumped to the mill and WTP. The West Zone pad is very level. A berm has been established between the West Zone Pad and the adjacent section of Brucejack Creek pad to provide physical separation of this infrastructure area from the creek.

Additional details on mine site water management and associated erosion control are provided in the Water Management Plan – Operations, Maintenance and Surveillance (OMS) Manual (Pretium 2021, Appendix 3-1-1-9).

The km 72 NPAG quarry east of the mine site is located in bedrock. The quarrying process results in excavated benches and walls in the sloping bedrock (Figure 3.3-7). The quarry is designed such that the final quarry faces will be stable.

Figure 3.3-3.Brucejack Mine Operations Contact Water Collection Area

3.4.1.3 Post-Mine Landforms and Drainage

Post-mine drainage catchments based on current closure planning, including based on consideration of post-closure water quality and on stability requirements for remaining water management structures, are shown on Figure 3.3-5. Following the removal of the active portions of the contact water collection system, the camp pad will drain passively to Camp Creek and the slopes below the mill, along with a portion of the mill pad, will drain to lower Camp Creek or to Brucejack Creek. The remainder of the mill pad and the areas passively draining to the CWP during operations will drain to the CWP and from there to the WRTSF. The CWP will remain in place, with the spillway remaining intact, and allowed to spill passively via the current emergency spillway, to the WRTSF. All areas east of the operations contact water collection system that drained passively to the WRTSF during operations will continue to do so post-closure. Post-closure, much of the mine site will continue to drain to the WRTSF, which will continue to passively collect and settle sediment. The West Zone Pad area will continue to drain to Brucejack Creek post-closure. Section 8.4.2 provides additional details of contact water collection area closure planning.

Mine closure and reclamation has been planned to facilitate movement of wildlife through the post-mining landscape (discussed below).

3.4.2 Transmission Line

Transmission line construction entailed very minimal surface disturbance and no significant effects on landforms. The Knipple substation was constructed on the pad (in gravel substrate) developed for Knipple transfer area and camp infrastructure (Figure 3.3-8). Much of this area had been previously leveled for the Granduc-Newcana joint venture use of this site for staging during the 1980s. The substation site is level, well drained (gravel and coarse textured materials substrate), stable and not subject to erosion.

Removal of the transmission line infrastructure at closure (towers, conductor, and Knipple substation) will result in the post- transmission line landforms being almost identical to the pre-mining landscape. There will be very minor and localized terrain changes compared to pre-development at some tower sites, but these are mainly limited to the vegetated southern portion of the line and are expected to become obscured by vegetation over time. The Knipple substation pad will be left level, in approximately the same topographical condition as existed prior to Pretium's use of this site. Erosion is not expected to be a significant consideration at any of the tower sites or at the substation.

Figure 3.3-8. Knipple Substation, July 2020.

3.5 REVEGETATION STRATEGY

3.5.1 Mine Site Area

Subject to the outcomes from ongoing reclamation research, the overall revegetation strategy for the Brucejack Mine site area is passive, and consistent both with the end land use objective of matrix habitat for mountain goat, grizzly bear, and hoary marmot, and with the challenges associated with local surficial materials. It entails creating, to the extent feasible and consistent with the pre-mine and adjacent landscapes, post-mine site and substrate conditions conducive to natural revegetation. Site disturbances will generally be recontoured and decompacted through shallow ripping as feasible and be allowed to regenerate naturally to locally endemic vegetation communities. Until the reclamation research program is sufficiently advanced to resolve active revegetation areas and methodologies, the reclamation plan and associated reclamation liability costing assume that mine site disturbances will generally be recontoured, de-compacted as feasible, seeded with the Brucejack high elevation native species seed mix, and fertilized (i.e. to supplement passive natural revegetation).

Most of the high elevation plant species that would be appropriate for an active revegetation program of the mine site are not commercially available and would likely present substantial propagation difficulties. Potentially suitable species that may be commercially available are very unlikely to have been sourced from near coastal northwest BC, and therefore, although the same species, may not necessarily be adapted to the site conditions at the Brucejack Mine site. These difficulties are further

exacerbated by the mine site surficial materials, which are acid generating or PAG, have elevated metals concentrations, and have been assessed as being unsuitable for use in reclamation (Section 3.2.1). The reclamation research program currently in progress is investigating the potential for revegetation of these materials to result in plant tissues with elevated metals concentrations, which, if these tissues are consumed by wildlife, could detract from the objective of providing suitable matrix habitat. Because of these limitations and challenges, passive or “leave-for-natural" revegetation approaches are more likely to yield acceptable long-term results than revegetation with non-local plant species. Further discussion on revegetation research and metal uptake is presented in Section 3.6 below on reclamation research.

The km 72 NPAG quarry and the BJAR segment between Knipple Glacier and the mine site (~km 71 to 73.3) were constructed mostly or entirely in rock. Natural revegetation is planned for these areas.

3.5.2 Transmission Line

During mine closure, the towers and conductor will be removed. As described in Section 3.2.2, transmission line towers within the northernmost 12.8 km of the transmission line are anchored into exposed bedrock. No revegetation is feasible or planned for these locations.

Most transmission line towers in the southern 6.7 km of the transmission line are also anchored in bedrock. The small, disturbed areas around tower sites with potential to support plant growth were seeded following transmission line construction. No reclamation specific to surficial materials is planned at these tower sites at closure beyond minor recontouring, including covering concrete foundations to the extent feasible, and additional seeding as appropriate. Wherever there are growth media available following removal of towers and lines at closure, these areas will be seeded with Pretium’s high elevation or low elevation seed mix (Table 3.4-1 and Table 3.4-2) as appropriate to the elevation (see Figure 3.4-1 as an example).

Because vegetation in the areas surrounding the towers has not been disturbed beyond felling trees (Figure 3.4-2), it is expected that any tower sites with surficial materials suitable for plant growth will revegetate naturally within a few years of transmission line removal, irrespective of any reclamation measures. The total area of tower bases and adjacent disturbed areas within the vegetated portion of the transmission line has been calculated at a total of 0.303 ha from analysis of site orthophotography. There are 13 towers in this section averaging 233 m^2 of surface disturbance per site (approximately 15 m by 15 m).

3.6 PROGRESSIVE RECLAMATION AND SEQUENCING

3.6.1 Mine Site

Design of the Brucejack Mine site has focussed on efficient and essential use of surface disturbances. The mine site surface disturbance area is small (mine site actual disturbance area totals approximately 55 ha), and the area is intensively used and needed for operations. Because Brucejack is an underground mine, incremental surface disturbances during mine life are very limited, and the site disturbance that is present is occupied by facilities and activities that will remain present throughout mine life.

An additional consideration within the small and intensively used mine site is the risk that revegetation efforts would pose to local wildlife. Establishing additional vegetation within the active mine site may attract hoary marmot and other small mammals, and possibly larger mammals such as bears. There is no feasible means to create barriers to prevent hoary marmot/small mammal ingress onto such areas, and this wildlife will be at increased risk of injury or mortality from traffic if present within the

active mine site. Further, as described in Section 3.7, results from the reclamation research in progress into metal uptake in vegetation is needed before there are efforts to establish vegetation within the gossanous area.

As a result of these factors, the opportunities for progressive reclamation within the primary facilities portion of mine site are currently mainly limited to those that will support reclamation research (see Section 3.7). This will be revisited as reclamation research proceeds and additional information becomes available. Areas within the M-243 PMA disturbed through surface exploration will continue to be reclaimed progressively (e.g., current Gossan Hill exploration areas north of Brucejack Creek, Figure 8.1-2). All other reclamation activities within the mine site will be completed during the closure phase.

3.6.2 Transmission Line

Tower sites within the southern 6.7 km vegetated portion of the M-243 authorized portion of the transmission line were seeded at the time each tower was completed. Vegetation disturbance between tower sites was limited to hand felling of trees due to use of helicopter support for line construction and absence of road access for all but a few tower sites within and near Knipple transfer area. Vegetation within the transmission line cleared width has been allowed to grow without further disturbance since the transmission line was completed (Figure 3.4-1).

Although vegetation regrowth at many tower sites has been excellent (Figure 3.4-2), there are small areas of limited growth at some tower sites. This appears in many cases to be related to bedrock presence at or near surface, or placement of compacted fill for certain tower sites (micro-piles) where tower anchoring to bedrock was not feasible.

The Knipple substation is located within the constructed gravel surface of the Knipple transfer area. The substation extent must remain vegetation free for as long as the substation remains active. M-243 portions of the Knipple pad outside of the substation will be active for life of mine as part of Knipple transfer area activities; this pad area is also tenured under License of Occupation (LOO) #6408836. Opportunities for progressive reclamation do not exist; all reclamation activities at this location will be completed during the closure phase.

3.7 RECLAMATION RESEARCH

3.7.1 Purpose and Objectives

The purpose of the Brucejack Mine reclamation research program is two-fold:

1. To address and reduce any identified uncertainties in the ability to achieve the objectives of the reclamation program, and
2. To test any key assumptions upon which successful reclamation is based.

Three primary and related uncertainties have been identified; these are the focus of the Brucejack reclamation research program over the next five years:

1. What is the potential for metal uptake in any vegetation that establishes on mine site surficial materials (i.e., naturally established or seeded vegetation);

2. Does any metal uptake that occurs pose or have the potential to pose concerns for any wildlife consuming this vegetation; and
3. Given the acid generating or PAG, and metalliferous characteristics of mine site surficial materials and their unsuitability on that basis as reclamation material, should there be active revegetation of the mine site as part of the mine-reclamation program (i.e., revegetation that would result in vegetation cover beyond what occurs naturally; potentially increasing the risk beyond what would occur naturally).

These uncertainties are inter-related in that findings from further research into metal uptake by plants could have implications for vegetation establishment on metalliferous mine site surficial materials. Reclamation research programs to address these uncertainties are discussed in more detail in the subsections below.

3.7.2 Trace Elements in Soils and Vegetation and Metal Uptake

Due to the mine site location on a gossan with mineralization to surface, trace elements in soils and growth media are elevated. Depending on the vegetation species and the trace elements that are present, metal uptake may occur. For example, soil size surficial materials (weathered parent material) and soils within the mine site are known to have elevated concentrations of arsenic. It is not expected that mine activities will significantly increase or change this. Surface stockpiling of excavated rock from the underground mine has been temporary and limited.

Waste rock is hauled directly to the shore of the WRTSF for subaqueous disposal, with stockpiling duration required to be maximum two years in accordance with M-243 Condition D.3(c)(v). Permanent disposal of waste rock on surface is not permitted. Snow cover and frozen conditions through most of the year and wet conditions through much of the remainder limits fugitive dust production and dispersal, as does the crushed NPAG rock surfacing of most site roads. Road watering is used as needed during the short summer season to limit road dust. Similar measures (road surfacing and watering) are used in the underground mine. There are pollution control works in the mill to manage dust sources there, in accordance with PA-107025 and the Air Quality Management Plan (Pretium 2022a, Appendix 3-1-1-2).

As noted above, surficial materials available as growth media within the mine site are PAG or acid generating, metalliferous, and have been recommended to not be used in reclamation. Research is in progress to provide more information on pre-mine conditions with respect to metals concentrations in vegetation, and to evaluate the implications and risks of revegetating site surficial materials.

As part of the terrestrial baseline program to support applications for mine authorizations, soils and vegetation were sampled at 11 sites in 2012 in the vicinity of the mine site area, and at six reference locations of similar elevation (ERM Rescan 2014) (Figure 3.6-1). Soil samples were collected at all sites, along with samples of the terrestrial lichen *Cladina stygia*. Samples of the blueberry *Vaccinium uliginosum* were also collected at one of the mine site sampling locations and at one reference site. Assessment of results from this sampling program indicate that all mine site soil samples and four of six of the reference sites had arsenic concentrations exceeding CCME industrial soil quality guidelines. There was some evidence of elevated arsenic concentrations in the lichen samples, although the occurrence of elevated levels was not as ubiquitous as in soil samples. Arsenic concentrations were below detection limits in the blueberry samples.

To advance understanding of the relationship between soil and vegetation element concentrations and the ability of vegetation to establish in metalliferous materials, a research program with five components is being conducted:

1. Sampling of surficial materials and vegetation once at the locations that were sampled in 2012, or where these sites no longer exist, at analogous locations (Figure 3.6-2).
2. Single-time sampling of surficial materials and vegetation co-located with the two historic dustfall canisters (Figure 3.6-2).
3. Opportunistic single-time sampling of surficial materials and vegetation at additional sites both within the gossanous surficial materials within/adjacent to the mine site area, and in adjacent non-gossanous areas for contrast (Figure 3.6-2).
4. Opportunistic single-time sampling of vegetation, and co-located sampling of surficial materials, that has established on disturbed materials within the mine site area [both gossanous and (thought to be) non-gossanous] (Figure 3.6-2).
5. Collection and removal of surficial materials for a greenhouse study using native grasses (the Brucejack Mine high elevation seed mix) to examine uptake in candidate species with potential for use in reclamation seeding within the mine site area.

Sampling programs 1 through 4 were completed during 2021, with results to be provided in the 2022 MA/EMA Permits Annual Report. Materials for the greenhouse study were collected from two locations in 2022 – the overburden stockpile and the vegetation establishment (i.e., seeding trial) area - and sent to Thompson Rivers University for initiation of research. In total, approximately 80 L of surficial materials were sent for testing and greenhouse propagation.

All surficial materials were, (or in the case of the greenhouse materials will be), analyzed for physical and chemical properties as described in Section 3.6.2.1 below. Vegetation sampling included re-sampling of *C. stygia* and *V. uliginosum* at sites previously sampled in 2012, and also included sampling of additional vascular species that could be consumed by hoary marmot. In total, 26 sites were sampled for vegetation in 2021, with a subset sampled for soils (Figure 3.6-2). Lichen samples were cleaned of non-lichen tissue and mineral materials prior to processing. All vegetation samples were analyzed for total element concentrations on a dry-weight basis by inductively coupled mass spectrometry (ICP-MS). This program is designed to be developed iteratively, so that results from initial sampling can be used to inform development of subsequent program phases as necessary.

Figure 3.6-1. Baseline 2012 Soils and Vegetation Sampling Locations and Approximate Outlines of Gossanous Surficial Materials

Figure 3.6-2. 2021 Trace Metal Sampling Locations and Approximate Outlines of Gossanous Surficial Materials

3.7.2.1 Vegetation Establishment

Research is in progress to identify opportunities to establish limited native vegetation cover on unamended local materials, such that any risks to wildlife due to metal uptake in vegetation are unlikely to exceed those present before mine development. As above, additional sampling of vegetation present within the gossan has been completed to improve the overall understanding of extent of risk. It is expected that as weathering and related acid production from surficial materials increases, the ability of the materials to support plant growth will decline until the acid has been depleted.

One study area, located south of the Brucejack upper camp, was identified to test revegetation establishment success and determine plant element uptake (Figure 3.6-3). Surficial materials were decompacted and the site was prepared for seeding. The site was then seeded with Pretium's high-elevation native seed mix (Table 3.4-2), which is tested for purity and to ensure lack of invasive species. The seed was applied at a rate of 60 kg/ha. As the disturbed soil had low organic-matter content and low fertility, fertilizer [16-16-16 nitrogen, phosphorus and potassium (NPK)] was applied at a rate of 40 kg/ha to promote plant establishment.

Approximately 40 L of surficial materials were composite-sampled from the seeding trial site and sent to Thompson Rivers University for analysis and inclusion in a greenhouse study (described in Section 3.6.2). Surficial materials will be described and tested for a range of physical and chemical parameters. Physical parameters will primarily consist of particle-size distribution. Chemical parameters will include pH, electrical conductivity, organic-matter content, total nitrogen, and a standard suite of analytes used for geochemical evaluation, including:

- total inorganic carbon,
- total carbon,
- sulphide sulphur,
- sulphate sulphur,
- total sulphur,
- insoluble sulphur (calculation),
- paste pH,
- modified neutralization potential (NP),
- acid production potential, carbonate acid NP and NP ratio (calculated),
- solid phase element by ICP-MS, and
- shake flask extraction (SFE).

The purpose of these analyses is to aid in interpretation of revegetation results, and to allow comparison to other materials that have been tested on site, including previously tested overburden and materials included in the metals uptake reclamation research program discussed in Section 3.6.2.

Results from the vegetation establishment study (i.e. plant establishment and element concentrations) will be monitored on an annual basis and reported in annual reclamation reports beginning with the 2023 annual report. Research trial approaches may be adjusted based on initial findings.

3.7.3 Implementation Schedule and Contingencies

As discussed above, repetition of the 2012 baseline soils and vegetation sampling was conducted in 2021, with results to be reported in the 2022 MA/EMA Permits Annual Report. Removal of materials for the greenhouse trial and installation of the vegetation-establishment trial was completed in August 2022, with initial results expected in 2023 and longer-term results expected for the establishment trial in subsequent years. This schedule is expected to meet reclamation needs, as opportunities for progressive reclamation are primarily limited to these areas; therefore, these research programs will provide information required for final reclamation at the end of mine life.

In terms of contingencies, there are two potential outcomes of the ongoing research:

1. Outcome 1: Research indicates that element uptake in vegetation remains below animal tolerance levels. In this case, active revegetation will be implemented on surface disturbances, using the high-elevation seed mix.
2. Outcome 2: Research indicates that element uptake in vegetation will pose a risk to animals consuming that vegetation due to the metalliferous nature of the gossanous surficial materials on site. In this case, surface disturbances will be left unvegetated, and allowed to revegetate naturally to the extent that may occur, to not magnify this risk.

Given the potentially acid-generating and metalliferous properties of the salvaged overburden, these materials are likely to be kept consolidated at surface and not spread as potential growth media. Active revegetation will be limited to residual materials in areas of surface disturbance and will consist of seeding of an appropriate seed mix (e.g., the current high-elevation seed mix, as adapted). No contingencies are proposed for revegetation success, as the mine-site area was sparsely or not vegetated prior to mining and passive revegetation will be the most successful mechanism for recovery of vegetated ecosystems and plant diversity on the post-mining landscape.

Figure 3.6-3. Site preparation completed at the vegetation-establishment trial, August 2022.

3.8 RECLAMATION MONITORING

3.8.1 Reclamation Success

Mines Act Permit M-243 directs that a reclamation success monitoring program be designed to evaluate the success of revegetation, landscape design, and erosion control, and that the program must specify sampling parameters and performance criteria. As noted, unlike most other mines in BC, the Brucejack Mine is an underground mine with small surface footprint that will remain active throughout the mine life. Also, atypical compared to other mines in the province, reclamation planning for the mine does not incorporate extensive ecological reclamation actions due to the harsh climate, lack of soils, and unsuitable nature of local surficial materials for supporting revegetation.

Thus, the reclamation monitoring program for Brucejack is focused on site specific reclamation objectives. The applicability of a revegetation monitoring program will be evaluated based on results from the metal uptake and revegetation research programs. Any modifications to objectives, and establishment of criteria applicable to reclamation monitoring, will be determined once interpreted results from the current reclamation research program yield more clarity on the most acceptable reclamation approach. As noted, soil salvage and replacement are not part of the reclamation program, as soil materials were extremely limited on the pre-mining landscape, and gossanous surficial materials are not suitable for use in reclamation cover systems.

Sediment from most of the mine site is well managed through mine design and implementation of the Water Management Plan – OMS Manual (Pretium 2021, Appendix 3-1-1-9). As described in Section 3.3.1.3, most of the mine site drains passively either directly to the WRTSF or to the WRTSF via the CWP and will continue to do so post-closure. A portion of the mine site is contained within the contact water management system, which captures runoff and ultimately directs it to treatment by the WTP prior to discharge to the WRTSF. Post-closure, some of the mine site drainage area will continue to report directly to the CWP, which will then discharge to the WRTSF. The remainder – primarily the mill and lower camp pads – will drain passively to Camp Creek or Brucejack Creek. These areas are dominantly bedrock or capped with NPAG crushed rock; erosion from these areas post-closure is not considered to be a significant consideration. Effectiveness of erosion control measures over the entire mine site is intensively monitored through the PE-107835 water quality monitoring program requirements, which include a stringent discharge limit for total suspended solids (TSS) at the WRTSF outlet and additional monitoring for TSS and other parameters in the downstream aquatic receiving environment. This monitoring provides rapid early warning of any significant erosion from locations not draining passively to the WRTSF or contained within the contact water management system. This monitoring program will continue through the closure period, thereby continuing to provide early warning of any significant site erosion during the active reclamation period.

Post-mine, pads, decommissioned roads (including drainage crossings), the km 72 NPAG quarry, the waste rock dump (WRD) pad, and other post-mine landscape features will be inspected for stability and performance. Repairs will be carried out if and as needed. This and other post-mine monitoring programs related to reclamation success are described in Section 12.

4 TRACE ELEMENT UPTAKE IN SOILS AND VEGETATION

Any ongoing monitoring of element uptake in soils and vegetation will be developed based on results from the current element uptake research program. The approach of this program, progress, implementation schedule, and contingencies are discussed in Section 3.6. Ongoing results will be provided in annual reclamation reports, and any required element uptake monitoring program will be presented as appropriate once an informed and robust approach can be developed from research program findings.

5 CONTAMINATED SITE REQUIREMENTS

There are no existing known or suspected areas of contamination at the Brucejack Mine site.

Hydrocarbon and chemical spill prevention at the Brucejack Mine is addressed through robust infrastructure spill prevention and secondary containment measures that include use of lined storage/dispensing facilities, secondary tank containment, routine inspection, and maintenance and other mitigation measures, as required and appropriate. Detailed storage and handling requirements and procedures for relevant substances at the mine are provided in Pretium's Chemicals and Materials Storage and Handling Plan (Pretium 2022a, Appendix 3-1-1-5).

In addition, Pretium implements its Spill Response Plan (Pretium 2022a, Appendix 3-1-1-7) through a rigorous site-wide spill response program. This program includes orientation in spill mitigation and response for all Pretium employees and contractors, distribution of spill response standard operating procedures (SOPs), augmented spill response training for select site personnel, equipping all vehicles and equipment with spill response kits and staging larger spill response equipment caches around the mine site area. Personnel are required and trained to clean up all spills that occur, and to report all spills internally, regardless of size. Dedicated collection and containment bins for hydrocarbon contaminated materials are sited at multiple locations at the mine site; these are processed and disposed of at an off site licensed facility. Spills exceeding prescribed quantities, or spills that enter, or are likely to enter a body of water, are reported externally in accordance with the *EMA* Spill Reporting Regulation (BC Reg. 221/2017). Water quality monitoring for hydrocarbons is conducted regularly at the final discharge point from the WRTSF (site BJ 3.10) and at the WTP. With these measures in place, the potential for significant residual spill-contaminated material presence at the mine during closure is considered to be low.

At closure, fuel, chemicals and other related substances no longer required will be returned to suppliers or disposed off-site at licensed facilities as appropriate, in accordance with Pretium's Chemicals and Materials Storage and Handling Plan (Pretium 2022a, Appendix 3-1-1-5). Following removal of liners beneath the Diesel Power Station (DPS) Pad and Sump, and beneath other fuel or chemicals storage or dispensing areas, Preliminary Site Investigations will be conducted in accordance with the Contaminated Sites Regulations (CSR) (BC Reg. 375/96) which includes sampling of relevant environmental media. Following the Preliminary Site Investigations, detailed Site Investigation(s) will be conducted if required. Remediation Plan(s) will be prepared and executed for any areas that the Detailed Site Investigation(s) deemed necessary as per the CSR (BC Reg. 375/96). Following this assessment process will ensure that reclamation success objectives and water quality requirements are satisfied, as per M-243 Condition E.6.

6 DISPOSAL OF TOXIC CHEMICALS, REAGENTS, HAZARDOUS MATERIALS, CONTAMINATED MATERIALS

Handling and storage of chemicals and reagents to be used on site are described in the Chemicals and Materials Storage and Handling Plan (Pretium 2022a, Appendix 3-1-1-5). At mine closure, any reagents and chemicals no longer needed for the mine will be packaged according to regulatory requirements and returned to the supplier or disposed of at a licensed off site facility following Pretium's Waste Management Plan (Pretium 2022a, Appendix 3-1-1-8). The on-site inventory of hazardous wastes will be actively managed through the later stages of mine operation to result in low quantities on site at the cessation of operations. Items that can be returned to the supplier or sold at cost will be returned/sold.

Spills during mine operations are immediately addressed following Pretium's Spill Response Plan (Pretium 2022a, Appendix 3-1-1-7), with the contaminated materials removed, contained and shipped off site to a licensed facility, or remediated in place and tested as appropriate. Any operational spills within containment areas are prevented or limited from migration outside of the containment area. These measures reduce the potential quantity of contaminated soil to be addressed at closure. Additionally, there is very little soil or overburden present at the Brucejack Mine site, facilities being largely constructed on bedrock and NPAG rockfill.

Areas suspected of potential contamination will assessed in accordance with the CSR (BC Reg. 375/96) as described above in Section 5 Contaminated Site Requirements. If contamination is identified through the Preliminary and Detailed Site Investigations, a Reclamation Plan will be prepared and executed. The Reclamation Plan will ensure that any contaminated soil materials identified at mine closure will be excavated and transported off site for disposal at a licensed facility in accordance with regulatory requirements and the above referenced management plans or, as appropriate, remediated on site.

7 GROUNDWATER WELL DECOMMISSIONING

Groundwater wells at the Brucejack Mine site include groundwater monitoring wells such as those required by PE-107835 and a potable water well that supplies the mine site camp and mine infrastructure.

At mine closure, selected groundwater monitoring wells will be left intact for closure and post-closure monitoring purposes. When groundwater wells are no longer required, they will be sealed in accordance with the requirements of the Groundwater Protection Regulation (BC Reg. 39/2016), *BC Water Sustainability Act* (2014).

8 RECLAMATION AND CLOSURE PRESCRIPTIONS

8.1 SUMMARY

8.1.1 Sequence and Schedule

Brucejack Mine closure activities are planned for implementation in a sequential manner such that infrastructure needed to the end of mine closure remains in place and all other reclamation activities occur in a logical progression. Key infrastructure to remain in place until confirmed to no longer be necessary are the WTP and infrastructure required to support it, including power supply, emergency generators, housing for WTP operators and support personnel and transportation infrastructure.

Final closure is expected to take approximately three years, including approximately two years of closure and reclamation activities within the M-243 disturbance area (primarily the mine site area), and an additional year of closing and reclaiming off-site ancillary infrastructure outside of the M-243 permitted area (Table 8.1-1). The latter includes the southern Statutory ROW portion of the transmission line and closing and reclaiming the BJAR and adjacent camps and infrastructure from km 59 to the intersection of the BJAR and Highway 37.

Reclamation activities within this period are planned and designed to provide for long term stable landforms and site conditions, and acceptable post-closure water quality in the Brucejack Creek aquatic receiving environment downstream of the mine. Underground mine reclamation, including removal of underground mobile equipment and completion of other pre-flooding preparatory measures, and flooding will begin immediately following closure (Table 8.1-2). Removal of surface equipment, buildings and infrastructure not required for water treatment and ongoing reclamation activities will occur during the first summer season of the closure phase. Surface reclamation will then be conducted as described below, including recontouring to prevent barriers or hazards to wildlife, establishment of stable post-closure surface drainage, and decompaction as appropriate.

Mine flooding is estimated to be complete within seven months based on accelerated flooding accomplished by water withdrawal from the WRTSF; the withdrawal rate will be to the current licensed rate during the winter low flow period, and at accelerated rates during the freshet high flow period. Water treatment of the underground mine pool will continue throughout the active flooding period, predicted to be an additional eight months (total 15 months) [(refer also to the Closure Underground Water Quality Adaptive Management Plan (Pretium 2020b, Appendix 4-2-2)]. Watertight plugs will be installed in the West Zone (WZ) and VOK portals, and in the raise planned north of Brucejack Creek, during the first year of the closure phase to allow underground mine flooding to its ultimate flooding elevation. The mine equilibrium flooding elevation is predicted to be approximately 1404 masl (seasonal variation from 1394 to 1412 masl).

The WTP and related facilities will be removed when water treatment is no longer required. Mine openings to surface (portals and raises) will be sealed within the first two summer seasons of the closure phase, when access is no longer required. Remaining surface reclamation will be completed by the end of the second summer, along with removal of remaining surface infrastructure and equipment, including the transmission line. Monitoring and reporting will continue throughout the closure phase and for ten years following completion of site reclamation.

**UG = underground mine*
**WT = water treatment

The Brucejack Mine site roads and the BJAR will be closed during the closure phase, therefore access for post-closure monitoring will be by helicopter. Post-closure monitoring will be carried out for site stability, surface and groundwater quality, aquatic resources, and reclamation success (including natural encroachment into facility areas by endemic vegetation). Geotechnical inspections will be conducted as required.

8.1.2 Mine Site Surface Reclamation

Mine reclamation at closure will begin with orderly and methodical removal of structures and equipment as described in detail in Section 8.2, except that required to support mine flooding and water treatment.

Most buildings and other infrastructure at the Brucejack Mine site are located on constructed pads (Table 8.1-3; Figure 8.1-1). The pads are stable, constructed with a combination of bedrock cuts (with excavated PAG surface material deposited into the WRTSF) and fill methods using NPAG quarried rock, or through placement of NPAG fill only. Off-pad facilities at the mine site include the upper camp area (including various offices and other, mostly modular, structures) CWP, site roads, contact water management infrastructure, overburden stockpile, WRTSF outlet weir, WRD, and the electrical services building, and other structures located in the low-lying area between the surface heavy shop and the Johnson Creek (East) diversion channel. Infrastructure within the upper camp area and warehouse and vicinity areas is mainly constructed on in-situ overburden, with several of these structures having been placed or constructed during advanced exploration or mine construction.

Table 8.1-3. Mine Site Constructed Pads and Infrastructure Areas.

Surface Infrastructure Pad	Area (ha)
Mill (including STPs) pad*	3.17
Lower camp pad*	2.39
VOK portal pad and storage *	1.01
Old heavy shop pad	0.60
Upper camp area (non-pad)	3.90
Upper camp bunk 6 pad*	1.04
Helipad and storage pads**	0.38
Main warehouse, electrical and waste sorting area	1.83
Diesel power station pad*	0.66
WZ portal pad**	2.31
Incinerator pad**	0.37
CWP	1.43
Truck shop pad	1.08
Total	**20.17**

*Combination cut and fill
**Fill only

Facilities pads within the mine site will be left in place at mine closure following removal of structures and equipment, with some recontouring of NPAG rock fill materials to reduce any potential for slumping and erosion and to support achievement of the end land use objective. In preparation for final reclamation, the mine site road surfaces, NPAG crushed rock cover on the pads, and low gradient areas near the Johnson Creek Diversion will be shallow ripped to reduce surface compaction, minimize surface erosion, allow for downward water infiltration, and create the conditions for such passive natural revegetation as may occur. Culverts will be removed from the roads and cross-drains and water bars will be established to create stable drainage. Figure 8.1-2 summarizes mine site area surface reclamation treatments at closure.

Recontouring and decompaction work during closure will be aimed primarily at preventing hazards or barriers to wildlife movement to achieve the end land use objective of wildlife matrix habitat (movement areas) particularly for mountain goat, grizzly bear, and hoary marmot (M-243, Condition E.3). These animals will be able to move across the mine site post-closure to access foraging areas or other habitat that provides life requisites. Reclamation work during closure will be secondarily aimed, to the extent feasible and suitable, at creating conditions for passive revegetation via propagules from local endemic vegetation species in adjacent areas. The Brucejack reclamation liability costing includes seeding much of the mine site using Pretium's high elevation native seed mixture, however a passive reclamation approach is preferred (refer to Section 3.6.3).

Contact water management infrastructure will remain in place until surface water collection and treatment are no longer required, at which time ditches not required for post-closure water management will be backfilled, pipeline and pumping infrastructure will be removed, and manholes will either be removed or rendered inactive. The seepage collection weirs below the lower camp pad will be breached or removed. The CWP, which is constructed in bedrock, will remain in place, and be allowed to spill passively via its spillway. The non-contact diversion channels will remain in place.

Waste rock dump development is planned such that most PAG rock will be placed subaqueously in the WRTSF during mine operations. At mine closure, remaining sections of exposed PAG rock on the dump pad will be placed subaqueously in a retreat manner, such that there are shallow ponded areas over much of the pad and exposed NPAG rock on surface near the shore of the WRTSF.

Figure 8.1-2. Mine Site Surface Reclamation Treatments

8.1.3 Underground Mine

At closure, all underground tanks and their contents will be removed and their contents shipped off site for re-use or shipment to licensed facilities. Hydrocarbons and hazardous materials from fixed equipment that is not being removed will also removed for off site shipment to licensed facilities. Fixed underground equipment suitable for re-use will be removed and transported off site. All mobile equipment and supplies will be removed from the underground mine and shipped off site for re-use or disposal as appropriate.

Most stopes will be backfilled with waste rock and paste tailings during operations. Flooding and water treatment during mine closure will occur as described in the Closure Underground Water Quality Adaptive Management Plan (Pretium 2020b, Appendix 4-2-2). At closure, the underground mine workings will be flooded over a period of approximately seven months. Water treatment of the underground mine pool is planned to continue for and additional eight months, for a total treatment duration of 15 months.

Both portals and the raise planned north of Brucejack Creek will be sealed with watertight plugs to enable the mine to flood to the predicted elevations. The portals and all raises will be sealed when no longer required for access. Any seepage from the plugs will be allowed to drain to Brucejack Creek / WRTSF.

8.1.4 Transmission Line

The Brucejack transmission line will remain in operation until this power supply is no longer required at the mine site; this is expected to follow the scheduled 15 months of closure phase water treatment. When no longer required, the Brucejack transmission line towers and conductor will be removed using helicopter support as necessary. Substation equipment and components will be removed using ground access. Transmission line and substation components will be transported off site for recycling or disposal as appropriate.

Within the southernmost 6.7 km section of the M-243 portion transmission line that is below treeline, there may be some disturbance of surficial materials in the areas around the tower bases during the dismantling of the towers. Any growth media that are disturbed will be seeded with either the high or low elevation seed mixture, as appropriate, and concrete foundations will be covered contingent on availability of suitable materials. Removal of transmission line structures over most of the M-243 transmission line section is not expected to result in significant ground disturbance nor effects on landforms, as these are anchored in rock. Post- transmission line and tower removal, all portions of the transmission line are expected to meet the wildlife matrix habitat end land use objective.

8.2 STRUCTURES AND EQUIPMENT

8.2.1 Introduction

This section describes the approaches that will be used to close the various mine structures, facilities, and equipment, including a description of decommissioning activities. Figure 8.2-1 shows mine site surface infrastructure within the mining leases at the end of 2022. Figure 8.2-2 provides a detailed view of the current mine site (2022) surface infrastructure.

Figure 8.2-2. Brucejack Mine Site 2022 - Detailed Infrastructure Plan

8.2.2 Underground Mine

Description

There are two portals: the VOK portal, located east of the mill building at 1408 masl, and the WZ portal, located at the western end of the WZ pad at 1365 masl (Figure 8.2-2). Four vent air raises are currently located within the mine site and one additional vent raise is planned during mine life north of Brucejack Creek, with the possible addition of a fresh air intake raise (Figure 8.2-2). Figure 8.2-3 shows a typical surface structure for a vent raise. The four existing raises are located in high elevation terrain southwest of the mine site and above the VOK zone, and the planned raise is located north of Brucejack Creek, east of the incinerator. The potential fresh air intake is located proximal to vent raise #1 (Figure 8.2-2).

Major underground mine infrastructure includes a grizzly, crusher, conveyor belts, ventilation fans, an electric air heating system (supplemented by propane heaters when required), electrical cables, transformers, pumping stations, water pipelines, paste backfill pipelines, water tanks, electrical substations, explosive magazines, refuge areas, mine communications, and other ancillary installations. Two 20,000 kg tanks store bulk emulsion at the explosives magazine loop, along with a third 20,000 kg mobile tank.

Figure 8.2-3. Surface Structure for Vent Raise.

Closure

At closure, all underground tanks including the fuel and emulsion tanks will be emptied and both the tanks and their contents taken off site for use by others or proper disposal following Pretium's Chemicals and Materials Storage and Handling Plan and Waste Management Plan (Pretium 2022a,

Appendix 3-1-1-5). Hazardous materials, fuels, oils and glycol from fixed equipment that is not being removed will be drained and/or removed, and then transported to surface for off site shipment to licensed facilities for disposal following the above referenced plans. Fixed underground equipment suitable for re-use will be removed and transported off site. All mobile equipment and supplies will be removed from the underground mine and shipped off site for re-use or disposal as appropriate.

Most stopes will be backfilled with waste rock and paste tailings during operations. Flooding and water treatment during mine closure is described in the Closure Underground Water Quality Adaptive Management Plan (Pretium 2020b, Appendix 4-2-2), and in the 4950 tpd Joint M-243/PE-107835 Amendments Application (Pretium 2022b, Appendices 5-2 and 5-3). At closure, the underground mine workings will be flooded over a period of approximately seven months. Flooding will be via natural groundwater recharge and water withdrawal from the WRTSF at the currently licensed rate (70 m^3/h) during the winter low flow months, augmented by accelerated water withdrawal from the WRTSF via pumping or siphoning into the portals during the freshet period. Water treatment of the underground mine pool is planned to continue for 15 months.

Watertight plugs will be installed inside each portal and in the raise planned north of Brucejack Creek to enable the mine to flood to the predicted equilibrium elevation of approximately 1404 masl elevation (varying seasonally between 1394 and 1412 masl) (Pretium 2022b, Appendix 5.1-3, Section 6.1.3). The WZ and VOK portals surface elevations are 1365 and 1408 masl respectively, and the surface elevation of the planned raise north of Brucejack Creek is 1392 masl. Any seepage from the portals and raise plugs will be allowed to drain to Brucejack Creek / WRTSF. All portals and raises will be sealed when no longer required for access.

8.2.3 Surface Structures and Equipment

8.2.3.1 General Closure and Reclamation Methods

This section describes general methods for closure and reclamation of surface buildings and other infrastructure. Current mine site surface buildings and infrastructure are shown on Figure 8.2-1 and Figure 8.2-2 and listed in Appendix 8.2-1; the latter includes key information pertinent to building deconstruction or demolition, and reclamation of building locations.

Surface buildings and infrastructure not required for water treatment and ongoing reclamation activities will be removed during the first summer season of the closure phase. The upper camp will be retained through the closure phase while other camp structures (and other mine site structures and equipment) are removed and the mine site is reclaimed. As the camp population declines, bunk 3 will be removed first, with bunk 6 and its adjacent communications infrastructure retained until water treatment and site reclamation are complete and final demobilization from the mine site is to take place. Temporary modifications will be made to the mill building to enable safe and efficient operation of the internal water treatment facilities while most of the building is removed.

Wastes generated through building deconstruction, demolition and related mine site closure activities will be handled and disposed in accordance with regulatory requirements and Pretium's Waste Management Plan (Pretium 2022a, Appendix 3-1-1-8) and Refuse Incinerator Management Plan (Pretium 2020b, Appendix 4-2-7). Table 8.2-1 summarizes waste types and disposal methods.

Table 8.2-1. Brucejack Mine Waste Types and Disposal Methods

Waste Type	Disposal				
	On site Incineration	Burn Pit	On site Disposal	Off site Facility[a]	Off site Recycling
Aerosol containers[b]				X	
Batteries[b]				X	X
Appliances					X
Clean cardboard (recyclable)					X

Vent bags					X
Waste fuel (gasoline, diesel)[b]				X	
Waste oil[b]	X				
Wiring					X
Wood (pallets, lumber)	X	X		X	X

Notes:
[a] Such as a landfill or other licenced facility appropriate for the waste.
[b] Hazardous waste
[c] HDPE lines in the WRTSF will be removed as feasible and disposed off site. Pipe will remain in place in the WRTSF if it cannot be removed.
[d] Oil contaminated rags containing less than 3% of oil by weight are permitted to be incinerated provided they do not exceed 0.2% of the total waste incinerated per year (EMA Air Permit PA-107025 Condition 1.7.5).
[e] Polyvinylchloride (PVC) plastic pipe will not be incinerated and will be disposed off site. Combustion of plastics will be minimized through waste reduction and recycling programs where feasible.
[f] Curtain material will be removed as feasible and disposed off site.
[g] Insulation foam is removed from the cladding on site and disposed separately off site.
[h] Empty totes will be sent off site for recycling or returned to the supplier. Spent chemical reagent bags will be incinerated or disposed of off site depending on the type of chemical reagent and all other plastic chemical containers will be incinerated.

Skirting, add-on roofs, and framed entrances will be removed and services disconnected from trailers, and then the modules will be transported off site for re-use or disposal as appropriate. Modular buildings (e.g. upper and lower camp complexes, Figure 8.2-4; Appendix 8.2-1) will be disassembled and the modules will be transported off site for possible sale and/or re-use. Modules unsuitable for re-use, along with structural steel, cladding, wood and other additions to trailers and modular structures will be handled as described below for non-modular buildings.

Steel cladding, structural steel and steel framing will be dismantled and processed on site, and subsequently removed and transported off site for recycling, or otherwise included with general non-hazardous demolition debris and transported off site for land-filling (see Table 8.2-1). Clean wood suitable for burning in accordance with the requirements of PA-107025 will be burned in the approved burn pits. Other re-usable and recyclable materials/equipment and will be transported off site (Table 8.2-1).

Figure 8.2-4. Modular Lower Camp Complex During Construction in 2016.

Contaminated site investigations will be conducted as described in Section 5. Hydrocarbon contaminated soil will be transported off site for disposal at a licensed facility or, as appropriate, remediated on site. Hazardous wastes will be transported off site for disposal at a licensed facility.

Buried services will be removed from site for recycling or landfilling as appropriate. Building footprints on fill or overburden will be recontoured as appropriate for stability and achieving the end land use, and decompacted as feasible and appropriate. Concrete foundations and/or pads will remain in place with adjacent pad materials or overburden graded to or near pad level to prevent barriers to wildlife movement, or hazards. Reclamation treatments at closure are summarized on Figure 8.1-2.

The subsections below describe methods specific to the main buildings, and infrastructure with additional reclamation considerations.

8.2.3.2 Building-Specific Methods

8.2.3.2.1 Mill

8.2.3.2.1.1 Description

The mill building (Figure 8.2-2 and Figure 8.2-5) is constructed with metal roof and wall cladding and installed on concrete grade beams and pedestals. It includes the facilities and equipment for ore processing, concentrate storage and load-out, WTP, paste plant, reagents storage, lab, warehouse, offices, and other associated equipment and supplies storage. An exterior conveyor carries crushed ore the VOK portal building to the mill building.

The WTP, housed at the northern end of the mill building, treats groundwater seepage and surface contact water collected in the CWP as per M-243 and PE-107835 requirements, along with process water. The WTP includes processing equipment, a chemical dosing system, storage tanks, agitators, and dosing pumps.

Figure 8.2-5. Mill, Conveyor to VOK Portal and VOK Portal (Photo August 2022).

8.2.3.2.1.2 Closure

All equipment except the WTP and pipelines and other connections required for its function will be removed from the mill building at closure. Reagents will be properly secured and removed off site to appropriate facilities unless required for WTP operations. Lubricants and oils will be drained from equipment and packaged for disposal at a licensed off site facility. Equipment will be transported off site and sent for recycling or reuse. Conveyors will be dismantled, and the metal components removed off site for sale or recycling. Conveyor belts will be disposed in the underground mine or transported off site for disposal at a licensed facility (landfill). Remaining supplies will be used for various closure

activities, as required. Any remaining reagents (i.e., that are not required for the WTP) will be taken off site for resale or disposal. The motors and pumps and other equipment will be removed and taken off site for reuse or recycling. Wiring and electrical equipment not required for WTP operations will be removed off site and taken to appropriate facilities for disposal. Any hazardous materials will be removed for disposal at off site licensed facilities.

Temporary modifications will be made to the mill building to enable safe and efficient operation of the internal water treatment facilities while most of the building is removed. The WTP and remaining mill building will remain in place for the 15 month water treatment period or until it has been confirmed that water treatment is no longer necessary. WTP sludge produced during closure will be transported off site and disposed at a licensed facility.

When water treatment is no longer needed, the water treatment plant equipment and other remaining interior equipment and structures will be removed from site for re-use or disposal. The remaining mill building will be dismantled and the metal siding and roofing will be removed off site for recycling or disposal. In the unlikely event of any spills being present around the building, a site investigation will be completed as described in Section 5 and the contaminated materials will be removed and disposed off site at licensed facilities; hydrocarbons may be treated on site as appropriate. The concrete floor of the mill will be left in place and surrounding pad materials will be graded onto it to prevent any barriers to movement.

8.2.3.2.2 Portal Structures

8.2.3.2.2.1 Description

The VOK portal is located east of the mill building at a surface elevation of 1408 masl (Figure 8.2-2 and Figure 8.2-6). The portal structure building contains an access portal, conveyor portal, mine air heaters, ventilation fans, the conveyor drive motor and mechanism, an electrical substation, and a monorail located in the ceiling of the building for the mine air fan motor and components. The roof and the sides of the building are constructed with metal cladding. The building is located on a concrete pad.

The WZ portal was originally developed in the 1980's by the Granduc-Newcana joint venture (with Newhawk as the operator), and is located near the western end of the WZ pad at a surface elevation of 1365 masl (Figure 8.2-7). It is the primary personnel and equipment access and is the waste rock haulage egress location. Infrastructure includes an access portal, mine air heaters, and ventilation fans.

Figure 8.2-6. VOK Portal Building, Tower and Conveyor Gallery (Photo July 2020).

Figure 8.2-7. West Zone Portal (Photo July 2020).

8.2.3.2.2.2 Closure

At closure, the conveyor connection from the VOK building to the mill will be removed and dis-assembled. If still suitable for use, the conveyor structure will be removed from site for re-use. If there is no re-purposing potential, the conveyor belt will be removed from site and appropriately disposed or may be placed in the underground mine. Re-usable components such as the mine air heaters, ventilation fans, conveyor mechanism and other equipment will be removed and transported off site for re-use; otherwise they will be disposed off site as appropriate. Building and conveyor steel structural components and cladding will be transported off site for re-use or recycling. Demolition debris will be transported off site for disposal as appropriate. The same approach will be used for the WZ portal infrastructure, as appropriate.

Concrete pads will remain in place and be addressed as described in Section 8.2.3.1.

Engineered watertight plugs will be installed in both portals at closure and both portals will be sealed to prevent access. The plugs will be designed to allow flooding to the predicted equilibrium average water level of 1404 masl (seasonal variation between 1394 and 1412 masl).

8.2.3.2.3 Lower Camp Complex

8.2.3.2.3.1 Description

The lower camp complex (Figure 8.2-2) is a multi-storey modular building with metal clad walls and roofs (Figure 8.2-8). The lower camp complex includes accommodations and associated facilities such as kitchen and dining, medical, reception, offices, recreational facilities, laundry, mine dry and mill dry. The lower camp complex buildings are constructed on steel platforms placed on top of pedestals anchored to bedrock or piles. Most of the complex (dorms, kitchen, and

recreation/medical/laundry/offices) is constructed from modules placed on top of the steel platforms. The mill dry and offices building, situated adjacent to the mill, was framed in place.

Figure 8.2-8. Lower Camp Complex (Photo September 2022).

8.2.3.2.3.2 Closure

All contents of the lower camp complex will be removed and shipped off site for re-use, recycling or disposal as appropriate. Exterior steel staircases, and steel roofing and cladding will be removed and transported off site for recycling or disposal as appropriate. Trailer modules will be disassembled and removed from site to be sold or disposed. The structural steel bases of the main lower camp building and steel floor and building frames for the mill dry/offices building will be removed and shipped off site for recycling or disposal. The concrete building pedestals will be cut off at their bases and buried in the rock fill portion of the pad. Electrical and piping service connections will be removed and recycled or disposed off site. Materials that can be recycled will be separated and taken off site for recycling. Materials suitable for landfilling will be taken off site to a licensed facility. Clean unpainted wood will be separate and burned in the burn pits if feasible.

8.2.3.2.4 Heavy Shops

8.2.3.2.4.1 Description

The current surface equipment heavy shop (Figure 8.2-2) is a wood frame and steel clad building constructed during advanced exploration (Figure 8.2-9). A second heavy shop, for underground mine equipment, is located on the WZ pad. The WZ heavy shop (Figure 8.2-2) is a mainly steel frame and clad building on a concrete slab (Figure 8.2-10). A new truck shop is under construction; it is a metal framed structure with metal cladding (Figure 8.2-11). The new truck shop will include 3 workshop bays for underground equipment, 2 workshop bays each for light vehicles and trucks, 2 tire shop bays, 1 wash bay, lube and oil storage, welding shop, office modules, fire protection room, electrical room, and warehouse on the ground floor. The service space lower and upper levels will include mechanical service space and area for offices, meeting room, washroom, lockers, lunchroom, tool crib, and maintenance shop wicket.

Figure 8.2-9. Surface Heavy Shop (Photo July 2020).

Figure 8.2-10. West Zone Heavy Shop (Photo July 2020).

Figure 8.2-11. New Truck Shop (Photo October 2022).

8.2.3.2.4.2 Closure

During closure, when no longer required, contents of the heavy shops, including all tools and equipment, will be removed from the mine site for reuse/resale. Oil, grease, and lubricants will be drained from the equipment and placed with other waste oils for removal from the site and recycling at a designated facility. Wiring and cables will be removed from the buildings and transported off site for disposal at an appropriate facility. Clean wood materials will be burned at the mine burn pit if separation is feasible. The interior metal structures such as shelving will be dismantled and taken off site for resale or metal recycling.

Metal framing, building sheathing and roofing will be removed and sent off site for recycling or disposal. Non-burnable wastes from building demolition will be removed from the site and disposed in a designated landfill. Concrete flooring at ground level will be left in place and adjacent pad fill materials will be graded even with the concrete pad. The floor slabs will be punctured utilizing heavy equipment to allow for long term drainage. Partial or complete pad covering will be completed if there are sufficient pad fill materials to accomplish this without compromising pad stability or causing other issues.

8.2.3.2.5 Waste Handling Facilities

8.2.3.2.5.1 Primary Waste Sorting and Staging Facility

The primary waste sorting and staging facility (Figure 8.2-2 and Figure 8.2-12) is a seacan and wood frame building, with exterior metal cladding and metal roofing, constructed on a concrete pad.

Figure 8.2-12. Primary Waste Sorting and Staging Facility (Photo July 2020).

8.2.3.2.5.2 Incinerator and Burn Pit

The Brucejack incinerator and waste sorting facility, and primary mine burn pit is located north of Brucejack Creek, northwest of the WZ pad (Figure 8.2-2). There is a bridge across Brucejack Creek to access the facility. The incinerator building is wood framed on a concrete pad with steel exterior cladding and roofing (Figure 8.2-13).

Figure 8.2-13. Incinerator and Waste Sorting Facility (Photo July 2020).

8.2.3.2.5.3 Closure

The waste handling facilities will not be removed until the final stages of building and facility removal during closure, as they are required to manage wastes produced during building deconstruction and

other closure activities. As waste collection and handling receptacles and large bins are no longer required, they will be shipped off site for re-use, recycling or disposal as appropriate. The primary waste sorting and staging facility building will be deconstructed or demolished in the same manner as other similarly constructed buildings, with metal cladding removed and transported off site for recycling or disposal, seacans removed and transported off site for re-use, clean burnable wood collected and burned in the burn pit, and insulation and other non-recyclable materials transported off site for landfilling. Adjacent surficial materials will be graded level with the concrete floor.

The incinerator will be removed off site once all demolition and clean-up has been completed and taken to a designated facility for disposal or sold for reuse. Remaining ash from the incinerator will be transported off site for disposal. The incinerator building will be de-constructed or demolished, with metal cladding removed and transported off site for recycling or disposal, insulation and any other non-recyclables transported off site and disposed as appropriate, and clean wood materials burned in the burn pit. The foundation and concrete floor of the incinerator will be left in place and adjacent pad materials will be graded level to it. The burn pit will be backfilled with pad/fill material.

8.2.3.2.6 Hydrocarbon Storage Facilities

8.2.3.2.6.1 Description

Hydrocarbons such as propane, diesel and gasoline are stored at several locations within the mine site area (Figure 8.2-2). Spill prevention, secondary containment and other measures are in place for these storage and dispensing facilities appropriate to the hydrocarbon types and quantities and in accordance with Pretium's Chemicals and Materials Storage and Handling Plan and Spill Response Plan (Pretium 2022a, Appendix 3-1-1-5 and 3-1-1-7).

The main hydrocarbon storage location is the DPS, located at the eastern end of the WZ pad, down-gradient of the mill pad (Figure 8.2-2). Back-up generators and associated fuel storage are located on the DPS pad, along with fuel storage and dispensing for surface equipment and light vehicles (Figure 8.2-14).

Figure 8.2-14. DPS Pad Facilities (Photo July 2020).

The DPS fuel storage is a lined facility where the discharge passes through an oil water separator system before discharge into the DPS sump, which is connected to the contact water management system. Tankage includes diesel to supply the backup diesel power generation system, and diesel

and gasoline dispensing tanks for equipment, light vehicles, small mobile equipment [boats, snowmobiles, all terrain vehicles (ATVs) and rugged terrain vehicles (RTVs)], and miscellaneous gas engine equipment (mobile generators). Another diesel dispensing tank is located near the WZ portal to service underground mine equipment and vehicles; that tank is also connected to the DPS oil water separator system.

Propane tanks are positioned on the lower camp and mill pads, and on the WZ pad to provide heat for surface buildings and the underground mine. An additional propane tank on the WZ pad supplies fuel for the incinerator and to heat the incinerator building.

8.2.3.2.6.2 Closure

At closure, the fuel tanks and any fuel remaining in the tanks will be collected and removed off site for recycling or repurposed. Precautions will be taken to minimize any potential for spills in accordance with Pretium's Chemicals and Materials Storage and Handling Plan and Spill Response Plan (Pretium 2022a, Appendix 3-1-1-5 and 3-1-1-7). Any spilled fuel on liner will be collected with the appropriate spill response materials and removed offsite for disposal at a licensed facility. Any hydrocarbon contaminated liner material will be removed and disposed offsite at a licensed facility. Clean liners will be cut and/or shredded and disposed of in the underground mine or shipped off site for disposal at a licensed facility. A contaminated site investigation of underlying materials will be completed as described in Section 5. If hydrocarbon contamination is found, additional investigation will be completed if required (refer to Section 5) and materials will be removed in accordance with CSR requirements and disposed in accordance with Pretium's Spill Response Plan (Pretium 2022a, Appendix 3-1-1-7), or treated on site as appropriate. Clean crush or surficial materials from the pad location will be regraded over the formerly lined ground surface. The concrete pad for WZ pad diesel dispensing will be left in place, with surrounding concrete barriers removed and pad materials graded to the concrete surface. A contaminated site investigation will be completed for this area as described in Section 5, including that smaller tank areas will be investigated for residual hydrocarbons. If hydrocarbon contamination is found, additional investigation will be completed if required (refer to Section 5) and materials will be removed in accordance with CSR requirements and disposed in accordance with Pretium's Spill Response Plan (Pretium 2022a, Appendix 3-1-1-7), or treated on site as appropriate.

8.2.3.2.7 Pipelines

8.2.3.2.7.1 Description

External (not contained in buildings) surface pipelines at the mine site include High-density polyethylene (HDPE) pipelines for the contact water management system, tailings discharge (twin lines) (Figure 8.2-2), WTP/sewage treatment plant (STP) influent and effluent discharge lines, direct emergency discharge line from the CWP, pipeline connection from the potable water supply well to the potable treatment facilities, and potable water distribution line. The tailings and effluent discharge lines extend into the ponded portion of the WRTSF, where the tailings lines are suspended within the WRTSF by cable systems (Figure 1-1). The tailings lines are partly buried along their surface extents.

8.2.3.2.7.2 Closure

During closure, the tailings and WTP/STP/CWP effluent discharge pipelines will be disconnected from the mill building and the CWP. Effluent pipelines disconnection will not occur until water treatment has concluded, and the potable water pipeline will remain in place until potable water supply via

pipeline is no longer required. Pipelines on land (outside the WRTSF) will be removed, cut up and taken off site for landfill disposal. The tailings pipeline cables will be removed via the winch systems, with the latter then removed from site for re-use or recycling. Pipeline sections within the WRTSF will removed to the extent feasible and disposed as described above; sections that cannot be removed will remain in the WRTSF.

8.3 WRTSF

8.3.1 Waste Rock and Tailings

8.3.1.1 Description

All mine surface and underground waste rock is managed as PAG in accordance with M-243 and Pretium's ML/ARD Management Plan (Pretium 2021, Appendix 3-1-1-6) and is required to be either backfilled in the underground mine below the ultimate flooding elevation or deposited subaqueously in the WRTSF (refer to M-243 Condition D.3.c.iii). WRTSF operations are conducted in accordance with applicable conditions in M-243 and the Waste Rock and Tailings Storage Facility OMS Manual (Pretium 2022a, Appendix 3-1-1-9). Figures 10-1 through 10-3 show the horizontal extents of the waste rock dump crest and toe for the years noted based on the 2022 mine plan presented in the 4950 tpd M-243/PE-107835 Joint Application (Pretium 2022b). Surface waste rock excavation from mine construction is complete and these materials have been placed in the WRTSF; subaqueous deposition of underground mine waste rock will be ongoing through mine life.

Waste rock may be stored subaerially for up to two years. Some is temporarily stored in surface stockpiles at the WRD as part of facility management, and some is used temporarily to surface the WRD, with the latter then replaced with either 'fresh' PAG rock or NPAG rock excavated from the km 72 NPAG quarry within the two year period. There are also provisions to leave exposed rock causeways on the WRD with shallow ponded sections in between; this approach has not been used to date and is more likely to occur late in mine life as the waste rock dump platform nears its maximum extent.

Tailings are NPAG and either piped into the underground mine where they are disposed as paste backfill in mined out stopes or discharged deep within the ponded portion of the WRTSF via the two tailings pipelines. Expected tailings extents throughout mine life, based on the 2022 mine plan, are also depicted on Figures 10-1 through 10-3.

8.3.1.2 Closure

Waste rock dump development is planned such that most PAG rock destined for the WRTSF will be placed subaqueously during mine operations. At mine closure, remaining sections of exposed PAG rock on the dump pad will be placed subaqueously in a retreat manner, such that there will be a shallow ponded area over much of the pad and exposed NPAG rock on surface near the shore of the WRTSF.

Tailings will remain submerged in the WRTSF. HDPE pipelines in the WRTSF and the tailings pipeline support cable system will be addressed as described above in Section 8.2.3.2.7. The WRTSF sediment curtain will be removed and these materials disposed off site at a licensed facility.

Most of the WRTSF will remain ponded at mine closure.

8.3.2 WRTSF Outlet Weir and Reclaim Pump System

8.3.2.1 Description

An instream concrete and steel weir structure is located at the WRTSF outlet with steel walkways and a steel building housing flow measurement equipment and the reclaim pump system (Figure 8.3-1). HDPE pipe and electrical service lines connect the weir to the mill building. The weir structure provides a means to accurately measure discharge rates from the WRTSF and a suitable location for water withdrawal and pumping from the WRTSF. Details of the weir are provided in the Water Management Plan - OMS Manual (Pretium 2021, Appendix 3-1-1-9).

Figure 8.3-1. WRTSF Outlet Weir (Photo July 2020).

8.3.2.2 Closure

The weir structure, building and water reclaim system will remain in place until the underground mine has flooded to its ultimate elevation and supplemental water withdrawal from the WRTSF is no longer required. The reclaim pumps and instrumentation will be removed from site for re-use or disposal at an appropriate facility. The weir building will be disassembled. Piping and unrecyclable building contents and components will be removed from site and disposed at appropriate facilities. The steel building and walkway components will be removed recycled or disposed at appropriate facilities. The concrete lock blocks that form a portion of the structure will be removed from site for re-use if they are still usable, and otherwise disposed within the exposed NPAG portion of the WRD pad. The central reinforced concrete portion of the weir will remain in place, where it is expected that it will be gradually covered by streambed sediments. Deconstruction and removal will be the opposite of construction, using a small temporary coffer dam structure to isolate the demolition activities from the flow in the stream.

8.4 CONTACT WATER POND, SURFACE WATER MANAGEMENT SYSTEM, AND WATERCOURSES

8.4.1 Description

Mine site water management infrastructure and function is described in detail in the Water Management Plan - OMS Manual (Pretium 2021, Appendix 3-1-1-9); a summary is provided in Section 2.5.5. There are approximately 2.5 km total of non-contact diversion channels at the mine site. The Camp Creek (West) and Johnson Creek (East) diversion channels (Figure 8.2-2) intercept surface runoff from outside of the primary mine infrastructure area and direct it to Brucejack Creek and the WRTSF, respectively. Both are engineered channels, partially constructed in bedrock and otherwise lined with geotextile and armored with riprap (Figure 8.4-1).

Figure 8.4-1. Camp Creek Diversion Channel (Photo July 2020).

The surface contact water management system collects surface runoff from areas of surface PAG rock excavation within the primary mine facilities area located between the diversion channels, and directs it to the CWP (refer to Pretium 2021, Appendix 3-1-1-9, for details). Water collection and conveyance infrastructure includes several unlined ditches constructed in bedrock, lined and riprapped ditches in fill or overburden (approximately 1.2 km of collection ditches in total), HDPE pipelines, two small concrete weirs down-gradient of the camp pad, several manholes and lined sumps, various pumps and culverts. The largest contact water management system pumps are located at the CWP. The 50,000 m^3 capacity CWP (Figure 8.4-2) is entirely excavated in bedrock, with no liner and a concrete covered bedrock spillway. Surface contact water is collected in the CWP and then piped to the WTP for treatment.

Figure 8.4-2. Contact Water Pond.

8.4.2 Closure

The non-contact diversion channels will remain in place for closure and post-closure. The surface contact water collection system will be disassembled during the first two summers of the closure phase, after which surface drainage will be passive toward the WRTSF, CWP, Brucejack Creek or Camp Creek. Pumps and HDPE pipes will be removed. The HDPE pipe will be cut up and transported off site for disposal at a licensed facility. Liner in ditches will be removed and disposed in the same way as the HDPE pipe.

Contact water collection ditches will be backfilled during the closure phase when their function is no longer required. The concrete water collection weirs below the camp pad will be breached and the water allowed to drain passively to Camp Creek.

The CWP and its pumping systems to the WTP will remain in place until use of the WTP is no longer required, to allow continued availability of the CWP as emergency storage in case of WTP upset conditions. When no longer required, the pumps will be removed off site and re-purposed or disposed at an appropriate facility. Remaining HDPE pipe will be removed and cut into sections and transported off site for disposal at a licensed facility. The CWP will remain in place, with the spillway remaining intact, and allowed to spill passively via the current emergency spillway, to the WRTSF. Safety berms installed around the mill pad and up-gradient of the CWP will remain in place.

8.5 OVERBURDEN STOCKPILE

Approximately 30,000 m^3 of overburden is stockpiled at the mine site, in one stockpile (Figure 8.2-2). As discussed in Section 3.2.1, this material is not currently recommended for use in final site reclamation. The current plan for this stockpile at closure is to recontour it to a lower profile that is less likely to erode.

8.6 KM 72 NPAG QUARRY

The km 72 NPAG quarry is located near the east end of the WRTSF (Figure 8.1-2); it occupies approximately 14 ha, is excavated in rock, and is benched into a steep, bedrock slope (Figure 3.3-7).

The NPAG quarry will remain in place post- closure. No reclamation measures are feasible.

8.7 SNOW DUMP

The snow dump is located outside of the gossanous area, between the km 72 NPAG quarry and mine site; it covers approximately 5.13 ha (Figure 8.1-2). The snow dump is where snow removed during mine site snow clearing activities is stockpiled due to lack of space for this within the mine site. Most of the material placed at the snow dump is snow and ice, however surficial road and pad materials are unavoidably mixed with the snow when surfaces are ploughed or excavated to the ground surface. This results in some accumulation of these materials at the snow dump site. The snow dump site is graded during the summer months to help accelerate melting.

Snow removal needs will decline significantly during closure, which is expected to allow remaining snow and ice in the snow dump to fully melt. Once snow and ice have melted to ground surface, the area will be decompacted as appropriate and the area will be seeded with Pretium's high elevation seed mix (Table 3.4-2).

8.8 ROAD RECLAMATION

8.8.1 Description

The BJAR, of which the ~km 71 to 73.3 section is located within the M-243 area (Figure 1-1 and Figure 8.2-1), will remain in use during closure until water treatment is no longer required and mine site area reclamation activities are complete. Other mine site area roads will remain in use during closure until access to facilities are no longer required.

8.8.2 Closure

Mine site area roads will be decommissioned and reclaimed when the infrastructure to which they provide access is no longer required. The last site roads to be closed will be those providing mine site access to the underground mine and to the WTP. As roads are decommissioned, culverts will be removed and cross drains installed to restore natural drainage and provide for stable post-mine drainage. Steel culverts will be taken off site for recycling or disposal. The areas where the culverts have been removed will be graded to provide stable slopes at exposed cuts and riprapped as appropriate. Road surfaces will be decompacted up to 15 cm (Figure 8.1-2) as appropriate and feasible, to allow for surface drainage and to reduce the potential of road surface failure with time. Ditches will be backfilled and graded to provide surface stability and reduce erosion potential.

8.9 BRUCEJACK TRANSMISSION LINE

The Brucejack transmission line will be dismantled when its power supply is no longer required. The towers will be de-strung and the tower conductor will be removed. Helicopters will be used to re-spool

and remove the conductors and to dismantle and remove the towers. Conductor and tower materials will be transported off site and recycled or disposed as appropriate. Substation equipment and components will be removed using ground access. Transmission line and substation components will be transported off site for recycling or disposal as appropriate. The substation fence will be removed, and the pad area will be decompacted and seeded with Pretium's low elevation seed mix (Table 3.4-1).

9 LONG-TERM STABILITY

Brucejack Mine infrastructure development areas and excavations in rock, such as the constructed surface infrastructure pads, underground mine workings and surface openings, the WRTSF, and the km 72 NPAG quarry, have been designed and constructed following professional geotechnical and other engineering practices, and in accordance with M-243 and Code requirements. Stable landforms require a stable foundation. Pre-construction geotechnical field investigations were completed to support engineering designs and the regulatory approval application process. Mine facilities and post-closure surface landforms sites are designed to remain stable throughout mine life and beyond through closure and post-closure.

Geotechnical monitoring programs are in place for underground mine ground control and the WRD during mine operations. A Subsidence Monitoring and Management Plan (Pretium 2020b, Appendix 4-2-8) is in place in accordance with M-243 Condition D.13. A post-closure geotechnical monitoring program will be developed as mine closure approaches.

Closure of facilities will be planned and implemented such that final structures and landforms will have long-term stability during post-closure. Surface water will be managed to reduce its effect on the constructed landforms. Diversion channels will remain in place to direct water away from the infrastructure pads and in a manner that will not cause surface erosion in adjacent areas. Water from within the contact water catchment will be allowed to drain passively to the WRTSF, CWP, Brucejack Creek and Camp Creek.

Watertight plugs will be installed at closure in the WZ and VOK portals, and in the raise north of Brucejack Creek. All portals and raises will be sealed to prevent access. Watertight plugs and seals will be engineered and designed to be structurally sound. All designed landforms and structures will be monitored for stability during operations and following closure.

10 FIVE YEAR MINE RECLAMATION PLAN

Design of the Brucejack Mine site has focussed on efficient and essential use of surface disturbances. The total surface disturbance area within the PMA is small (terrestrial infrastructure area of 55 ha) (Section 8.1.2; Figure 8.1-1) and is almost entirely needed for operations. Because of this small, intensively used footprint, revegetation has not been possible to date within the mine's primary infrastructure area and there are no foreseeable opportunities for progressive reclamation in the next five years beyond the small areas being used to support reclamation research (see Section 3.7). Almost all reclamation within the PMA will be completed during the mine closure. Reclamation at mine closure is described in Section 8.

Outside of the primary infrastructure area, progressive reclamation of areas disturbed through surface exploration will continue (e.g., current Gossan Hill exploration areas north of Brucejack Creek, Figure 8.1-2). The surface exploration disturbance is much less intensive than within the primary facilities area, and extents within the PMA are very small as most exploration proximal to the mine is conducted underground.

Surface layouts for end of 2023, 2025 and end of mine (end of 2029) are shown on Figures Figure 10-1, Figure 10-2, and Figure 10-3 respectively. Development of a second WRD at the east end of the WRTSF, with associated access and temporary surface waste rock stockpiles, is planned to begin in 2023 subject to regulatory authorization. This infrastructure, including progressive extents of the WRDs (south and east) is shown on these figures. A 5th ventilation raise is planned north of Brucejack Creek for 2025; this is shown on Figures Figure 10-2 and Figure 10-3. As is the case with the mine's primary infrastructure area, this additional infrastructure will be required for the duration of mine operations.

At closure, following subaqueous deposition of all PAG waste rock, the east WRD access and temporary PAG waste rock stockpile sites will be shallow ripped to reduce surface compaction, minimize surface erosion, allow for downward water infiltration, and create the conditions for such passive natural revegetation as may occur. Culverts will be removed from the access road and cross-drains and water bars will be established to create stable drainage. Figure 8.1-2 summarizes surface reclamation treatments for this area at closure. Although the proposed additional east WRD associated access and stockpile locations are situated outside of the gossanous area, the area is primarily exposed bedrock or rocky terrain with very little vegetation cover. Nonetheless, as is the case with the other mine site surface disturbance areas, reclamation work during closure will be aimed, to the extent feasible and suitable, at creating conditions for passive revegetation via propagules from local endemic vegetation species in adjacent areas (i.e., a passive reclamation approach is preferred; refer to Section 3.6.3.).

Figure 10-1 Mine Site Area Surface Plan End of 2023

Figure 10-2 Mine Site Area Surface Plan End of 2025

Figure 10-3 Mine Site Area Surface Plan End of 2029

11 TEMPORARY CLOSURE

In the event of a temporary shutdown, irrespective of length, a small contingent of 40 to 50 personnel per rotation (80 to 100 total) will remain on site to implement care and maintenance activities, including ongoing mine dewatering and associated water treatment, and to maintain site access and security. This is necessary for environmental protection purposes and to protect the considerable investment in site infrastructure and equipment. Fuel will be removed from equipment that is not required and removed for off site disposal. The VOK portal building will be secured to prevent portal access, and the WZ portal will be gated and secured. All vent raises have metal screens to prevent access; therefore, no additional measures will be needed for these. Site security systems will remain operational.

Road and transmission line monitoring and maintenance will continue. The gate at the Bell-Irving River crossing near Highway 37 will be kept locked to prevent unauthorized access to the BJAR and the mine and will be monitored for signs of unlawful entry. The gate at Wildfire security will be kept secured.

Table 11-1 lists the minimum contingent of personnel planned to be retained at the Brucejack Mine in case of temporary closure.

Table 11-1. Brucejack Mine Temporary Closure List of Personnel

Position/Title	Base Location	# Personnel (x 2 for cross-shifts)
Mine Manager	Mine Site	1
Environmental Manager	Mine Site	1
Surface Operations Manager	Mine Site	1
H&S Superintendent	Mine Site	1
Mountain Safety	Varies	3
Mine Captain	Mine Site	2
Underground Miners (for dewatering and UG maintenance)	Mine Site	4
Environmental Technicians	Mine Site	2
Environmental Technicians	Knipple Camp	2
Water Treatment Plant Operators	Mine Site	2
Sewage Treatment Plant Operators	Mine Site	1
Maintenance Personnel (including skilled trades)	Mine Site	6
Equipment Operators	Mine Site / Knipple Camp	6
Camp Personnel (Kitchen & Accommodations)	Mine Site	6
Camp Personnel	Knipple Camp	3
Camp Personnel / Caretaker / Security	Wildfire Camp	2
TOTAL		43

If an extended temporary shutdown of the mine occurs that lasts longer than one year, constructed pads and slopes will be checked for stability and erosion and any areas requiring maintenance will be

treated. WRD operations will be continued until all subaerially exposed waste rock has been subaqueously disposed in accordance with M-243 requirements. A long-term care and maintenance plan will be prepared for regulatory approval.

At times of temporary halts to mine operations, ML/ARD management will be continued, including operation of the WTP. As well, the following will be implemented to reduce or mitigate potential ML/ARD risk:

- Subaqueous deposition of subaerially exposed rock will be continued;
- Any remaining tailings will be disposed of in the WRTSF or underground; and
- Any remaining WTP sludge that cannot be co-mingled with tailings for discharge to the WRTSF will be transported off site for disposal at a licensed facility.

In the event of temporary shut-down periods, access to and along the BJAR will continue to be managed to minimize indirect mortality (i.e., hunting) of wildlife. Signs will be posted to indicate access closure warnings. The mine infrastructure will also be managed by removing wildlife attractants and through continued implementation and enforcement of the Environmental Management System component management plans.

12 POST-CLOSURE MONITORING AND MAINTENANCE

12.1 OVERVIEW

Monitoring is required under Section 10.7.21 of the Code to demonstrate that reclamation and environmental protection objectives including land use, productivity, water quality, and stability of structures are being achieved. Mine closure is estimated to be completed within three years, followed by post-closure monitoring over the following ten years. The results of the monitoring program are to be included in the Annual Reclamation Report (per Section 10.4.4 of the Code).

The following is a description of conceptual post-closure monitoring plans planned for the Brucejack Mine. The length of time required for monitoring may be extended if the early results of the program indicate further monitoring is required. All facilities will be dismantled and/or removed from site during closure with site drainage and landforms contoured to a final closed state. As such, regular maintenance is not anticipated. Maintenance needs will be identified on an as-needed basis based on the monitoring and inspection programs described below.

Monitoring programs will be designed to address evolving needs and are anticipated to decrease in scope through the closure and post-closure periods. During the closure period, monitoring programs will focus on monitoring and management of reclamation activities. During the post-closure period, monitoring programs will focus on demonstrating reclamation success. The general scope of monitoring programs will include:

- Surface water quality and quantity, sediments, and aquatic biological resources;
- Groundwater quality and levels, including water chemistry and level in the underground mine as feasible;
- Structural integrity of portals and raise watertight plugs;
- Geotechnical assessment of post-mine landform and watercourse stability, including for the surface above the underground mine (subsidence); and
- Assessments of reclamation program success in meeting the end land use objectives.

Additional details are provided in the subsections below.

12.2 SURFACE WATER QUALITY AND QUANTITY, SEDIMENTS, AND AQUATIC BIOLOGICAL RESOURCES

Surface water quality and quantity, sediments and aquatic biological resources monitoring and sampling will continue to follow the requirements of PE-107835 through the closure period, with the exception of the reference site (L3 outflow) and effluent discharges as these cease (first tailings, then mine water and CWP influents and WTP effluent once water treatment has concluded, and finally treated domestic wastewater once the site has been fully closed). Once there is no longer a presence at the Brucejack site, surface water quality and quantity (flow) monitoring will continue twice per year (spring/fall) and sediments and aquatic biological sampling will be conducted every second year (biennially) until the end of the first ten years of the post-closure period.

12.3 GROUNDWATER

Monitoring of select groundwater installations will occur during the active closure and post-closure periods. Currently, PE-107835 stipulates the completion of four additional groundwater monitoring wells at closure, with an installation plan submitted two years prior to closure.

The number of groundwater quality sampling stations and monitoring frequency during active and post-closure periods will be established in consultation with BC Ministry of Environment and Climate Change Strategy (MECCS) and BC Ministry of Energy, Mines and Petroleum Resources (MEMPR). During active closure, new and existing wells situated immediately downgradient of the mine workings are recommended for more frequent (i.e., quarterly) monitoring events, while wells situated farther from the mine are recommended for biannual monitoring. During the first ten years of the post-closure period, it is recommended that biannual water quality monitoring be implemented across the well network. Biannual monitoring events are recommended in early June and late September, bookending the open water season.

During the groundwater monitoring events, it is recommended that groundwater sampling crews undertake visual inspections of the West Zone and VOK portals to identify and photograph any seeps potentially created by the recovering mine pool. If channelized flow exists, it is recommended that crews measure flows and field parameters (pH, EC) and collected samples comprising the routine groundwater analyte suite.

Water level data will be collected at locations earmarked for groundwater quality sampling and additional monitoring installations as agreed upon with MECCS and MEMPR. All monitoring stations will be equipped with dedicated dataloggers for continuous water level monitoring and will be downloaded during sampling events, safe access permitting.

Monitoring of underground mine pool is outlined in the Closure Underground Water Quality Adaptive Management Plan which is updated every five years and will be finalized two years prior to closure, as stipulated in PE-107835. During the post-closure period, discrete sampling of the mine pool from multiple depths is recommended from one or more vent raises. Sampling frequency is recommended to coincide with groundwater quality sampling events. Continuous monitoring of mine pool elevation and electrical conductivity, as a surrogate for water quality, is recommended from one or more dataloggers.

Water level data collected from monitoring installation and mine pool will be used to validate and/or update the numerical groundwater model, thereby facilitating prediction of the location and volumetric flux of contact water migrating from the underground to Brucejack Creek. Water quality monitoring of the mine pool and downgradient monitoring wells will inform conceptualization of geochemical loadings to Brucejack Creek.

12.4 MINE OPENINGS

The structural integrity of the watertight plugs in the WZ and VOK portals and the raise north of Brucejack Creek will be checked prior to placement of exterior seals at the end of the closure period to ensure these are performing as required and designed. Repairs will be carried out if and as needed.

12.5 GEOTECHNICAL

Geotechnical monitoring, inspection and assessment of post-mine landforms will continue annually during closure and for the first ten years of post-closure. Implementation of the Subsidence Monitoring and Management Plan (Pretium 2020b, Appendix 4-2-8) will continue through closure, and with a modified program appropriate to post-closure, and as approved by MEMPR, implemented during the first ten years of post-closure. The CWP and its spillway, and post-mine watercourses (particularly the two diversion channels) will continue to be inspected annually for structural integrity and performance. Post-mine, pads, decommissioned roads (including drainage crossings), the km 72 NPAG quarry, the WRD pad, and other post-mine landscape features will be inspected for stability and performance. Repairs will be carried out if and as needed.

12.6 RECLAMATION PROGRAM

Monitoring and assessments of the reclamation program success in meeting the end land use objectives will be conducted annually during the first ten years of post-closure. This will include monitoring for erosion, particularly any determined to affect surface water quality downstream of the WRTSF discharge, and remediation as appropriate. The mine site area will be inspected to confirm that closure measures implemented to achieve the end land use objective of matrix habitat remain intact, with remedial measures implemented as appropriate as necessary. Natural locally endemic vegetation species encroachment onto the mine site will be monitored and documented.

12.7 POST-CLOSURE PERSONNEL REQUIREMENTS AND ACCESS

Since regular maintenance is not anticipated post-closure, limited personnel are required. During the first-year post-closure, there will be 1 full time Environmental Manager and 1 full time Project Manager. For subsequent years, both the Environmental Manager and Project Manager time allocation will be reduced to 25%. During the ten years post-closure, additional support will be received from consultants. The Environmental Manager, Project Manager, and consultants will be based offsite and helicopter transportation will be used for post-closure site access.

Post-closure monitoring will require personnel and access to site twice per year for surface water quality monitoring, four times over ten years for sediment and aquatics monitoring, quarterly for groundwater monitoring, and annually for mine openings, geotechnical, and reclamation monitoring.

LORAX ENVIRONMENTAL

Executive Summary

Introduction

The Brucejack groundwater model has been updated in support of a proposed ore production increase for Brucejack Mine from 3800 tonnes per day (tpd) to 4950 tpd. This document describes updates to the numerical groundwater model performed in support of the Brucejack Mine 4950 tpd Joint *Mines Act* Permit (M-243) and *Environmental Management Act* Effluent Permit (PE-107835) Amendments Application (4950 tpd Joint Application). Results from this modeling work have been used to inform water balance and water quality model updates supporting the application.

The 3800 tpd groundwater model underwent a major update in 2020 in support of the 5 Year Mine Plan and Reclamation Program Update (2020 Update). Methods and findings of this study were presented in a stand-alone groundwater modeling report appended to the submission. The 2020 groundwater model superseded the 2015 permitting model which had informed the 2018 amendment application for an increased ore throughput from 2700 tpd to 3800 tpd.

The 4950 tpd groundwater model differs from the 2020 groundwater model in that it incorporates as-built mine plan and climate information to the end of 2021 and implements the 4950 tpd mine plan for future predictions. The model setup and parameterization otherwise remain identical to the 2020 groundwater model.

Model Calibration

The Brucejack groundwater model has benefitted from a comprehensive environmental monitoring program that includes daily record keeping of underground dewatering rates and dedicated water level logger deployment at all active monitoring wells. The monitoring program has revealed strong seasonality in groundwater levels and underground dewatering rates and long-term data trends consistent with a groundwater system that is being depressurized from depth.

The 2020 groundwater model was calibrated for both baseline and as-built mining operations periods. The baseline model simulated steady state water levels from 20 groundwater installations and baseflow in Brucejack Creek. The 2020 model provided an acceptable calibration to both targets.

The as-built operations model simulated the 2011 to 2018 period, with special focus on matching underground dewatering rates between 2015 and 2018 during which active mining occurred. The model incorporated the as-built mine progression on a monthly time

step. Along with the measured dewatering rates, transient groundwater level data from 21 monitoring wells were used as calibration targets. This dynamic data record capturing groundwater system response to seasonal and long-term hydraulic stress served as a powerful tool for calibrating bedrock hydraulic parameters and recharge rates. Over the calibration period, the 2020 model reasonably simulated both the magnitude and seasonality of underground dewatering rates, as well as seasonal and long-term trends in key monitoring locations near the Valley of the Kings (VOK) and West Zone workings.

Model Validation

Data collected from 2019 through 2021 have been used to validate the 2020 groundwater model. This data set includes underground dewatering rates and continuous water level data collected from 30 monitoring wells. Twelve of these wells comprise 2018-series monitoring wells whose data were not available for the calibration period. In this way, data from the 2018 monitoring wells serve to independently validate model performance. As-built mine progression over the 2019 to 2021 period was approximated in the groundwater model with groundwater recharge rates adjusted to reflect recent climate conditions.

Over the validation period, the model reasonably simulates peak underground dewatering rates but overpredicts annual minima by 450 m^3/d to 900 m^3/d. Over the calibration and validation period (2015 to 2021), the model overpredicted cumulative dewatered volumes by about 13% (3.92 Mm^3 vs. 3.47 Mm^3). Overall, the simulated dewatering rates are considered acceptable and reasonably conservative for estimating treatment requirements. Good performance of the model against observed water level data collected since 2018, particularly at locations where prior water level data did not exist, further enhances model credibility. As such, it was deemed unnecessary to recalibrate the groundwater model.

Future Operations Predictions

The 4950 tpd mine plan follows an average 3800 tpd production rate until January 2024 and then increases throughput to an average of 4950 tpd until the end of operations in December 2029. The 3800 tpd model simulated mining though the end of 2032. The 4950 tpd underground mine extents are similar to the 3800 tpd mine extents with the following differences:

- The VOK extends 30 m deeper and 175 m to the northeast on account of mining extension areas of the Brucejack mineralization;
- New exploration developments extend farther east, west and south than exploration developments included in the 3800 tpd mine plan; and,
- A tunnel is advanced from the West Zone to north of Brucejack Creek to establish a vent raise.

The 4950 tpd model predicts dewatering rates will stabilize over the last three years of mine life (2027 to 2029), ranging annually between 2,600 m^3/d and 4,300 m^3/d (30 L/s to 50 L/s). The 4950 tpd rates are marginally higher (by about 2 L/s) in the low flow period (April) than those predicted for the 3800 tpd mine plan. Cumulatively, the 4950 tpd model simulates 15% less extracted groundwater over the life of mine than the 3800 tpd mine plan due to a shorter mine life. Monitoring well water levels are drawn down on average 15 m more than the 3800 tpd mine at end of operations. Baseflow in Brucejack Creek is predicted to decrease during operations, stabilizing approximately 7 L/s (or 12%) lower than baseline at BJ 3.10 and 20 L/s (or 25%) lower than baseline at BJ 1.74. This baseflow reduction does not account for any increase in flow resulting from deposition of tailings and waste rock in the WRTSF. Predicted baseflow reductions are similar for both 4950 tpd and 3800 tpd models and the 2015 permitting groundwater model.

Closure Predictions

The 4950 tpd groundwater model simulates the passive reflooding of the mine by groundwater only, starting in 2030. Active reflooding of the mine using reclaim water is handled separately in the water balance model. Under passive flooding, the mine pool is predicted to recover to its equilibrium level around 23 months after onset of flooding. This is several months faster than what was predicted for the 3800 tpd mine plan. The equilibrium water level in the 4950 tpd mine is expected to vary seasonally between 1394 masl and 1412 masl, averaging 1401 masl, provided plugs are installed at the VOK and West Zone portals and in the vent raise daylighting north of Brucejack Creek. This is consistent with the equilibrium water level predicted for the 3800 tpd mine plan.

The equilibrium contact water flux issuing from the flooded 4950 tpd mine void varies seasonally between 10.4 L/s and 22.9 L/s, averaging 14.9 L/s annually. This is 4.7 L/s higher than what was predicted by the 3800 tpd model. The increase in contact water flux arises from an overall larger and deeper mine excavation, advancement of the vent raise north of Brucejack Creek and exploration developments. The majority of contact water reports to Brucejack Creek between BJ 2.62 and BJ 3.10, with some contact water reporting below BJ 2.62 and to the WRTSF itself. For the purpose of arriving at conservative water quality model predictions and thus an aggressive treatment strategy, an upper end value of 95% contact water flow reporting above 2.62 is assumed in the water quality model.

Baseflow is predicted to recover within 5% of baseline levels approximately three years after the end of operations, which is in line with predictions from the 3800 tpd model. Therefore, findings of earlier effects assessment on surface water quantity in Brucejack Creek remain valid with respect to predicted changes in baseflow quantity.

Model Sensitivity and Uncertainty

A sensitivity analysis carried out on the 3800 tpd model remains valid for the 4950 tpd model since the calibration has not been updated and the revised mine plan produces similar results as the 3800 tpd model. Having benefitted from several years of high quality calibration data, the analysis found that even modest (two-fold) changes in global hydraulic conductivity are not supported. Changes in fault hydraulic conductivity did not result in material changes in model predictions. Plug hydraulic conductivity will impact contact water fluxes and mine pool elevation only when increased well above a reasonably attainable value. Overall, the sensitivity analysis supports the use of the calibrated model moving forward in predictions and suggests that any future modifications of model properties will likely only need to occur on a localized scale.

Model uncertainty was assessed by examining the forecasted dewatering rates of the 2020 model against observed dewatering data from 2019 to 2021. The uncertainty arises from differences in planned and executed mine plan, average and experienced climate and general model parameterization. When expressed as a percent of observed rates, the model overestimates winter low flow rates on the order of 90% while open water flow rates are overestimated on the order of 30%. When the as-built mine plan and climate are simulated (by the 4950 tpd model), the winter low flow rates remain overestimated by 90% while open water season dewatering rates are essentially replicated. The conservativeness of the groundwater model is considered appropriate for the objectives it is seeking to fulfil.

Continued collection of groundwater level data and daily tracking of mine water management volumes will be instrumental in future groundwater model validation. It is recommended that future updates of the groundwater model include new faults which may impart non-trivial hydrogeological influence on the mine. Focus should also be placed on resolving the disparity between simulated and observed winter dewatering rates.

Authorship

This update to the Brucejack Mine Groundwater Model was prepared by Lorax Environmental Services Ltd. (Lorax) for Pretium Resources Inc. (Pretium), a member of the Newcrest Group of companies. The report was written by Laura-Lee Findlater, B.Sc., P.Geo., and Joseph Xu, Ph.D., and reviewed by Alison Shaw, Ph.D., P.Geo. Lorax Environmental Services Ltd. has relied on information available in scientific literature and information supplied by Pretium in preparing this report.

Glossary and Abbreviations

Terminology used in this document is defined where it is first used. The following list will assist readers who may choose to review only portions of the document.

asl	above sea level
EMA	*Environmental Management Act*
K	hydraulic conductivity
km	kilometre
L/s	litres per second
m	metre
m bgs	metres below ground surface
m^3/d	metres cubed per day
m/s	metres per second
MA	*Mines Act*
MAP	mean annual precipitation
mm	millimetres
NRMSE	normalized root mean square error
Pretium	Pretium Resources Inc.
PCIC	Pacific Climate Impacts Consortium
Q_{base}	baseflow simulated by the water balance model
tpd	tonnes per day
VOK	Valley of the Kings
VWP	vibrating wire piezometer
WRTSF	Waste Rock and Tailings Storage Facility

1. Introduction

1.1 Background

The Brucejack Mine (the mine), located in northwest British Columbia (BC), is a high-grade underground gold and silver mine operated by Pretium Resources Inc. (Pretium), a member of the Newcrest Group of companies. The mine is located approximately 60 km north-northwest of Stewart (Figure 1-1).

The mine received its BC Environmental Assessment Certificate (EAC) (#M15-01) in March 2015, and received *Mines Act* Permit (M-243) and *Environmental Management Act* Effluent Permit (PE-107835) in July and August 2015, respectively. Construction was initiated in September 2015 and commercial production was achieved in July 2017. M-243 was amended in December 2018 to increase the average ore production rate from 2700 tpd to 3800 tpd.

Numerical groundwater modeling of the mine was undertaken between 2013 and 2015 to support the EAC and *Mines Act*/*Environmental Management Act* (*MA/EMA*) permits applications (BGC, 2014c, 2015). Mine dewatering rates predicted by the 2015 groundwater model were later adjusted for the production increase presented in the 2018 *Mines Act* Permit Amendment (Pretium, 2018).

Pretium submitted its first 5 Year Mine Plan and Reclamation Program Update in 2020 (2020 Update) (Pretium, 2020). The numerical groundwater model underwent a significant update in support of the 2020 Update where it was migrated into a different modeling platform, refined and recalibrated to data collected up until the end of 2018 (Lorax, 2020b). Future predictions were provided for a mine plan that was primarily based on the 2019 Technical Report on the Brucejack Mine (2019 Technical Report; Jones *et al.*, 2019) with the addition of underground exploration development that was planned over the next five years.

Pretium is seeking amendments to permits M-243 and PE-107835 to increase its ore production rate from 3800 tpd to 4950 tpd (4950 tpd Joint Application). The numerical groundwater model has been updated to inform water balance and water quality modeling studies supporting the amendment application. The numerical model has been validated against data collected up until the end of 2021 and simulates the updated 4950 tpd mine plan. This document describes updates to the numerical groundwater model performed in support of the 4950 tpd Joint Application.

1.2 Scope of Work

The purpose of this report is to summarize the methods and findings of the 4950 tpd Joint Application numerical groundwater model. More specifically, this report provides:

- A summary of hydrogeological setting of the mine including hydrogeological data collected through the end of 2021 that has been used to update and validate the 4950 tpd model;
- A summary of model setup and predictions for the baseline period, which are unchanged from those presented in the 2021 model update;
- Updated model results for the current operations period extending to the end of 2021;
- Updated predictions of dewatering rates and groundwater levels during future operations under the increased production rate;
- Updated predictions of mine flooding time, volume and spatial distribution of contact water fluxes to Brucejack Creek and groundwater elevations during closure and post-closure; and,
- Updated predictions of baseflow impacts in Brucejack Creek arising from mine operations and closure.

The results of the 4950 tpd predictive simulations have been compared to corresponding predictions from the 2020 groundwater model to quantify changes in impacts on groundwater arising from the production increase. Updated groundwater model predictions have been used to inform updates to the site-wide water balance and water quality models (Lorax, 2023a,b).

2. Hydrogeological Setting

2.1 Physiography

The Brucejack Mine is located in the Boundary Range of the Coast Mountain Physiographic Belt. Mine infrastructure is located at 1360 to 1415 metres above sea level (masl) along Brucejack Creek and immediately southwest of the Brucejack Waste Rock and Tailings Storage Facility (WRTSF; Figure 2-1). The mine site is above treeline and lies in a transition zone between the very wet coastal and drier interior regions of BC. This part of northwestern BC is dominated by weather systems generated from the Pacific Ocean but is also strongly influenced by orographic effects caused by the local mountain topography that produces high spatial variability in snowfall, precipitation, temperatures and snowmelt. In addition, the extensive glacial areas around the mine site can impact snowmelt rates and produce high runoff volumes during the summer months. The humid climate and physical characteristics of the region result in dynamic streams and rivers with high annual runoff rates and high average stream flows.

2.2 Climate

Three sources of climate data were used to inform the Brucejack groundwater model: period of record weather data recorded at climate stations operated by Pretium; monthly synthetic climate data obtained from ClimateBC; and, daily gridded climate data available from the Pacific Climate Impacts Consortium (PCIC). These climate data are fully described in the water balance model reports prepared for the 2020 Update and 4950 tpd permit amendment application (Lorax, 2020a, 2023a). Summaries of mine site and ClimateBC data are presented in the sections below.

2.2.1 VOK Climate Station

The Valley of the Kings (VOK) weather station (1500 masl) and snow course are situated adjacent to the mine site and most relevant to the set-up and execution of the Brucejack groundwater model. Pretium also operates climate stations at two low elevation locations: Bowser Lake and Scott Pass (Figure 2-1). The VOK climate station is instrumented with research grade sensors and programmed hourly to record the following parameters: air temperature, relative humidity, average wind speed and gusts, solar radiation, net radiation, atmospheric pressure, and total precipitation. These data are essentially continuous, and high-quality, for the period of record September 2014 through December 2022. Monthly precipitation measured at the VOK climate station since 2015 is summarized in Table 2-1.

2.2.2 ClimateBC

The ClimateBC data tool generates synthetic climate data for use in water resources applications and climate change studies in British Columbia. Methodologies related to Climate BC are summarized in Wang *et al.* (2012). To support the 2020 update of the groundwater model (Lorax, 2020b), precipitation and potential evaporation data were extracted for grid points within the Brucejack Creek watershed. Extracted data spanned 100 m elevation bands between 1300 masl to >2000 masl. Consistent with BGC (2017a), raw precipitation outputs from ClimateBC were found to overestimate local precipitation depths within the Brucejack watershed. The raw outputs were adjusted to reflect 'true' conditions at the mine site, using the five years (2015-2019) of reference data at the VOK climate station as a guide.

Representative orographic gradients for the Brucejack Creek watershed were derived from the extracted data according to the UBC Watershed Model Manual (Quick *et al.*, 1995). Winter precipitation gradients were determined to be 3% per 100 m gain in elevation, summer precipitation gradients were computed to be 2% per 100 m gain in elevation, and potential evaporation gradients were determined to be on the order of negative 3% per 100 m elevation gain for applicable months (*i.e.*, May to September). Representative outputs from ClimateBC are summarized for three elevation ranges (or bands) within the Brucejack Creek watershed for precipitation (Table 2-2) and potential evaporation (Table 2-3).

A comparison between ClimateBC outputs (1983-2018) and measured VOK station data (2015-2019) is shown in Figure 2-2. ClimateBC estimates long-term mean annual

precipitation (MAP) for the mine site on the order of 1,950 for VOK station elevation which is higher than the average MAP measured at the VOK since 2015 (Table 2-2). Therefore, the long-term average MAP simulated by ClimateBC is an appropriate and conservative metric to inform groundwater recharge rates in the numerical groundwater model.

Table 2-2:
ClimateBC outputs of precipitation, Brucejack Creek Watershed

Elevation Band (masl)	% Area of WRTSF Basin	Precipitation (mm)												
		Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Annual

Figure 2-2: Time series comparing ClimateBC outputs and 2015-2019 measured precipitation for VOK climate station.

2.3 Hydrology/Baseflow Regime

Four lines of evidence were used to define baseflow conditions in local tributaries and the 2020 groundwater model: measured and synthetic streamflow data for the BJL-H1 hydrometric station (8.5 km^2) established by Rescan in 2010; 2014 to 2019 measured streamflow data for hydrometric stations established by Pretium at BJ 3.10 (6.5 km^2) and BJ 1.74 (8.5 km^2) (Figure 2-1); modelled outputs from a calibrated surface watershed model for the Brucejack Creek watershed; and, regional streamflow data for Water Survey of Canada gauge 08DD001 (Unuk River near Stewart, 1960-96; 1,480 km^2).

2.3.1 Previous Assessment

A hydrology assessment was undertaken for the Brucejack property in 2010 (Rescan, 2011) and updated in 2013 for an Environmental Assessment supporting the neighboring KSM project (Rescan, 2013). The assessments presented measured and synthetic flow data from the BJL-H1 monitoring station downstream from the WRTSF (Figure 2-1). Ultimately, the average of January and February synthetic low flows, 0.073 m^3/s, was used to evaluate the baseflow simulated by the 2015 groundwater model (BGC, 2015).

2.3.2 Measured Data

Every year since 2016, Pretium has submitted an annual monitoring report for the prior calendar year summarizing monitoring data and current state of understanding with respect to streamflow conditions within the Brucejack Creek watershed (*e.g.*, Pretium, 2022). The locations of relevant streamflow gauges are shown for reference in Figure 2-1, including gauges situated at location BJ 3.10 (record period 2014-present) and further afield at BJ 1.74 (2008-present). Since 2016, flows have been measured at BJ 3.10 by a weir, which includes a heated control house.

Patterns of streamflow at BJ 3.10 and BJ 1.74 are strongly influenced by snow accumulation and snowmelt processes, where roughly 85% of runoff on an annual basis is expected to report to receivers between May and the end of October. By comparison, runoff depths for other months of the year (*i.e.*, November through April) are much lower. Winter streamflow volumes are well characterized at the mine and at BJ 3.10 typically range from 0.050-0.120 m^3/s between December and April (Figure 2-3, Table 2-4).

Table 2-4:
Summary of streamflow measurements at BJ 3.10 (2014-2019).

Figure 2-3: Time series showing measured discharge at BJ 3.10 (2014-2019).

2.3.3 Surface Watershed Model Outputs

2.3.3.1 Approach

A modified version of the Birkenes watershed model (Christophersen and Seip, 1982) is used in the site wide water balance model to replicate the streamflow regime at the mine (Figure 2-4, left panel). The Birkenes model represents the watershed using a series of connected reservoirs which aim to replicate a measured hydrograph by separating total discharge into three component flows (Figure 2-4, right panel): quick flow, or event runoff, which may be associated with melting of snowpack or summer storms; interflow, which is flow through shallow overburden material and soils; and baseflow, which in concept is the portion of the hydrograph which is derived from groundwater discharge.

Figure 2-4: Overview schematic of the Birkenes 3-reservoir model (left) and conceptual hydrograph with partitioning of total flow to component parts of quick flow, interflow and baseflow (right).

As outlined in Lorax (2020a, 2023a), the site wide water balance model reads in a long-term daily climate dataset, developed from the PNWNAmet dataset accessible from the Pacific Climate Impacts Consortium (PCIC) data portal. The gridded data span the period 1945 to 2012 and are described by Werner *et al.* (2019).

Conceptually, incoming precipitation is partitioned in the Birkenes model to rain or a snow reservoir based on air temperature thresholds. Rainfall is directed into Fast and Slow Surface reservoirs, which represent areas of fast runoff response, and slower-draining soil areas, respectively. Fast and slow surface recession flow from the surface storage reservoirs can go directly to surface discharge, or to the deep surface water reservoir, depending on the fraction of remaining available storage in the latter. When the deep surface water reservoir contains water, slow recession flow from the reservoir reports as baseflow. Withdrawals from these reservoirs are governed by constant proportional losses applied to the reservoir volume at a given time-step. As the reservoir volume is drawn down (assuming no additional inputs), the rate of withdrawal is reduced, and thus the outflow signature approximates a negative exponential decay function (*i.e.*, the recession curve).

Snow within the snowfall reservoir remains in storage until snowmelt begins, which is controlled in the model using daily temperature-dependent melt functions. When snow within the snowfall reservoir melts, these waters can either report to other model reservoirs if they are depleted or generate quick flow following the mechanisms described for rainfall.

Over the course of a simulation, evaporation is withdrawn from both surface reservoirs (fast and slow), and from the deep surface water reservoir, but at a lower rate. Similar to the handling for snow versus rain, evaporation is computed in the model using temperature-based controls.

2.3.3.2 Outputs

Two outputs from the calibrated watershed model were used in the development of the 2020 groundwater model: annual average estimates of baseflow (Q_{base}) at the BJ 3.10 monitoring location (Figure 2-1); and, average monthly estimates of rainfall plus snowmelt (Table 2-5).

The annual average baseflow estimated from the surface water balance model is considered representative of the long-term groundwater contribution to the catchment water balance making it a suitable calibration target for the average conditions simulated by the baseline groundwater model. For a 67-year simulation spanning the daily climate record from PCIC, average annual baseflow at BJ 3.10 was computed to be 61 L/s, ranging between a minimum of 50 L/s to a maximum of 92 L/s. The 61 L/s annual average baseflow computes to an average yield of 9.3 L/s/km^2, which is similar in magnitude to period of record minimum and lower quartile flows for the Unuk River (~10 L/s/km^2).

The average monthly rainfall plus snowmelt presented in Table 2-5 was used to constrain the calibration of monthly recharge values employed in the groundwater model. Rain plus snowmelt results obtained from the calibrated Brucejack Creek watershed model indicate a majority (65%) of the annual event water signature reports in May (501 mm) and June (775 mm), with essentially all the remaining event water realized in July, August, September, and October (Table 2-5).

2.4 Hydrostratigraphy

2.4.1 Geology

The geology of the mine area is summarized in BGC (2015) and expanded upon in Shaw *et al.* (2020). The mine area is largely underlain by volcano-sedimentary rocks of the Lower

Jurassic Hazelton Group. These rocks unconformably overlie volcanic arc sedimentary rocks of the Upper Triassic Stuhini Group. Mine site geology is shown in Figure 2-1. A simplified list of the main lithologies encountered within the mine area includes the following:

- P1 [Office or Bridge]: Hornblende, feldspar phyric latite flows.
- P2: Megacrystic, plagioclase, potassium-feldspar, and hornblende phyric flow.
- V12 [Fragmental volcanics]: Hornblende and/or feldspar phyric latite to andesite fragmental volcanic rocks and subordinate flows with minor ash and lapilli tuff.
- S3-Poly [Polymictic conglomerate]: Heterolithic boulder to coarse cobble conglomerate with sandstone.
- Silicified Cap: Silicified rocks; typically, poorly sorted heterolithic conglomerate, lesser sandstone, and local mudstone; commonly includes rhyolite fragments.
- VSF [Volcanic Sedimentary Facies]: Volcanically derived siltstone and sandstone with minor arenite and pebble conglomerate.

The surficial materials within the Brucejack area consist of a sparse veneer of well-graded glacial till overlying bedrock. Grain size varies from sand to gravel, with some silt and clay, and variable quantities of cobbles and boulders. The thickness of unconsolidated deposits varies at the site but is generally less than 5 m and commonly less than 1 m (BGC, 2014b).

2.4.2 Major Structures

The fault model provided at the time of the 2020 model development included four large (*i.e.,* mine-scale) fault zones intersecting the mine area: the Brucejack Fault Zone, the Rainy Fault, the Valley of the Kings Main Thrust Fault, and the Upper Thrust Fault (Figure 2-1). A fifth major fault, the Bruce Fault, which follows the trace of Brucejack Creek, was simulated in the original permit model (BGC, 2015) and carried forward into the 2020 model and 4950 tpd update.

The Brucejack Fault Zone is a long lived northerly striking anastomosing vertical fault zone with predominantly left lateral strike slip movement showing a net displacement varying between 500 and 800 m (ERSi, 2010). It is comprised of a core of highly fractured rock with a zone of less fractured, fault-disturbed rock mass on either side. The width of the fault zone varies with depth and along strike from approximately 5 to 40 m and the fault is considered to be continuous along strike.

The Rainy Fault, Valley of the Kings Main Thrust Fault and Upper Thrust Fault are three gently dipping south-southwest striking faults. The Rainy Fault has an average thickness of 2 m, with the thickness appearing to increase with depth. Often the Rainy Fault zone is comprised of multiple gouge zones separated by more competent zones of very blocky rock mass. Seepage conditions within the zone vary significantly, from dry to dripping, hence the moniker "Rainy".

Pretium staff (Travis Murphy P.Geo, Operations Manager, pers. communication) indicate that the Rainy Fault is the most commonly encountered fault within the mine workings and is typically grouted when encountered in the mine workings for geotechnical purposes. The Rainy Fault intersects a significant amount of mine workings between the 1200 m elevation to the 1350 m elevation, while the VOK Main Thrust intersects workings only on the 1440 m elevation and the 1470 m elevation. The Upper Thrust lies above the current mine workings and is only identified through diamond drill core. Mine workings intersected the Brucejack Fault in August 2022.

The Bruce Fault, a west-trending fault occupying Brucejack Creek, was identified during 1990s era exploration (McPherson *et al.*, 1994) (Figure 2-1). More recent but still limited data for this structure suggests it is subvertical and possibly comprised of two splays. The faults vary from 0.2 m to 1.5 m thick with moderately gouged fault planes and strongly deformed rubble zones.

2.4.3 Hydraulic Conductivity

The site hydraulic conductivity database is comprised of over 150 measurements and draws from several hydrogeological and geotechnical field programs completed between 2010 and 2018 (BGC, 2014b, 2017, 2019). Test data are tabulated in Appendix A with results plotted versus depth in Figure 2-5. Figure 2-5 is split into three panels with the top panel showing all test data (including tests on overburden), the middle panel showing tests from faulted/fractured rock and the bottom panel showing tests from intact rock without faults or fractures. The determination of whether an interval was fractured or faulted was based on notes in borehole logs indicating whether these features were encountered. Borehole logs for monitoring wells for which hydraulic tests were completed are included in Appendix B.

Figure 2-5: Hydraulic conductivity versus depth at Brucejack Mine in faulted (middle panel) and non-faulted (lower panel) rock. Upper panel shows all tests results (including overburden).

Overall, the data suggest bedrock hydraulic conductivity decreases with depth but at any given depth, hydraulic conductivity is highly variable. For example, between 0 m and 100 m depth, hydraulic conductivity ranges from 3E-09 m/s to 1.5E-05 m/s; between 400 m and 500 m, hydraulic conductivity ranges from 2E-08 m/s to 1E-06 m/s.

Figure 2-6 groups the hydraulic testing results by lithology. The most frequently tested unit is the intrusives (49), followed by VSF (31), fragmental volcanics (30) and conglomerate (9). The data do not indicate a strong correlation between hydraulic conductivity and lithology; however, this is partially confounded by the number of tests available for different units for any given depth. The data also indicate that faulted rock intervals are not universally highly conductive.

Figure 2-6: Hydraulic conductivity by lithology at Brucejack Mine.

2.5 Groundwater Levels

Numerous monitoring wells have been installed across the Brucejack Mine (Table 2-6) (Appendix B) in several hydrogeological campaigns (BGC, 2014a,b, 2017, 2019). Per PE-107835, high-resolution water level data are collected from the monitoring well network via dedicated loggers and are presented in annual monitoring reports, the most recent of which was submitted in 2022 (Lorax, 2022 in Pretium, 2022). Water level and vertical gradient time series from currently monitored wells are provided in Appendix C. Water level data up to the end of 2018 were used to calibrate the 2020 groundwater model prepared for the 2020 Update (Lorax, 2020b). Water level data collected between 2018 and 2021 have been used to validate the 4950 tpd groundwater model.

June 2021 water levels are contoured in (Figure 2-7). Continuous dewatering of the VOK and West Zone workings has created a marked depression of the groundwater table in the footprint of the workings and farther afield. For wells where 2012 baseline data exist, annual drawdown based on June water levels have been computed (Table 2-6). The largest decline in water levels has been measured at wells upgradient of the VOK, namely BJ-GW11-5A/B and BJ-GW12-12A. These wells are currently dry and actual drawdown at these stations is inferred to be higher than that reported in Table 2-7 (*i.e.*, exceeding 100 m) based on water levels measured at BJ-GW18-19A (~1310 masl).

East of the West Zone, water levels at BJ-GW11-3A and BJ-GW18-17A/B are lower than the elevation of the WRTSF (1364.5 masl) which suggests that the WRTSF is currently recharging groundwater at its outlet.

Several wells where groundwater levels have declined due to mining have recently stabilized or partially recovered in the last three years (BJ-GW11-1A/B, BJ-GW11-3A, BJ-GW11-6B, BJ-GW12-8A/B, BJ-GW12-9B) (Appendix C). This has been attributed to higher precipitation from 2019 to 2021 than in the preceding three years (Table 2-1). Conversely, a few wells experienced notable drops in peak water levels in 2021 including BJ-GW12-11B, BJ-GW18-19B and BJ-GW18-21B, presumably due to expansion and deepening of the VOK workings. West of the Brucejack Fault, water levels at BJ-GW18-20A/B do not appear to be responding to mining which suggests that that the fault is limiting westward depressurization of the groundwater system.

Vertical hydraulic gradients are strongly downward (up to 80%) at most well locations; these downward gradients have either developed or strengthened on account of dewatering of the underground. Several wells demonstrated consistent or seasonally upward gradients, including BJ-GW14-14A/B and BJ-GW12-8A/B, located west of the Brucejack Fault.

Table 2-6:
Summary of new and historic monitoring well installations at the Brucejack Mine.

Monitoring Well ID	Reference	Install Date	Easting[1] (m)	Northing[1] (m)	Ground Surface[1] (masl)	Slotted Interval (m bgs)		Slotted Interval (masl)		Baseline Calibration Target[2]	WL Currently Monitored	Notes

2.6 Underground Dewatering Rates

Between 1986 and 1991, the Granduc Newcana Joint Venture, with Newhawk as the operator, advanced approximately 5 km of exploratory underground development in the West Zone. In late 2011, under the ownership of Pretium, the historic underground development was dewatered to assess conditions of the workings and determine if the workings could be used as a launching point for a development drive to the Valley of the Kings. Dewatering was halted several months thereafter, then resumed in September 2012 and has been continuous since then.

The mine collects and maintains a database of water managed by the water treatment plant, from which underground dewatering rates are determined. Water pumped from the underground is conveyed from a series of sumps located in VOK and West Zone workings to a single aggregating sump where it is then pumped to the water treatment plant. A portion of the flow is recirculated back to the underground via the underground waterbox. The groundwater component of underground dewatering rates is thus computed by subtracting flows to the underground waterbox from the totalized flows directed to the treatment plant. Monthly average dewatering rates are shown in Figure 2-8 and tabulated in Appendix D.

Potential water losses that are not captured in the dewatering rates which may lead to an underestimation of flows include moisture transported with saturated ore and waste rock to the mill and WRTSF, respectively, and humidity losses via mine ventilation. The first two losses are not constrained but assumed to be negligible whereas ventilation losses have most recently been estimated to be on the order of ~130 m^3/d. During low flow months (March-April), ventilation losses could lead to an underestimation of underground inflow rates on the order of 20%.

The underground dewatering record presented in Figure 2-8 illustrates the seasonality in dewatering rates. Annual minima are generally experienced in March or April and typically range from 500 m^3/d to 750 m^3/d (5.8 L/s to 8.7 L/s). Expansion of the mine void has not increased seasonal minimum inflows to date. Peak monthly mine inflows generally occur in June or July but can also occur later in the summer. Until the end of 2019, peak monthly inflows ranged from 1,800 m^3/d to 2,230 m^3/d (20.8 L/s to 25.8 L/s). In the last two years, these maximum rates have climbed over 2,500 m^3/d. The maximum experienced in June 2021 is attributed to a large rain-on-snow event that occurred late May/early June, which is apparent in a plot comparing daily inflows to climate metrics for 2021 (Figure 2-9).

The daily underground dewatering record for 2021 (Figure 2-9) demonstrates flashiness that is typical of other years. The flashiness is attributed to several factors including precipitation, mining rate, mining elevation, ground conditions and other operational artefacts. Rapid upticks in dewatering rates in response to heavy rainfall events as

experienced in June 2021 have also been noted previously in annual monitoring reports, suggesting a component of fracture driven flow to the underground.

Figure 2-8: Monthly underground dewatering rates for 2012-2021.

Figure 2-9: 2021 daily underground dewatering rates, daily rainfall and snow water equivalent (SWE).

2.7 Groundwater Quality

Groundwater quality is monitored at the Brucejack Mine per PE-107835 and summarized in annual monitoring reports (Lorax, 2022 in Pretium, 2022). Impacts from mining on current groundwater quality are limited. Dewatering of the underground caused slight shifts in major ion chemistry at historic VOK wells prior to the wells going dry (BJ-GW11-5A/B and BJ-GW12-12A). This manifested as higher proportions of sulphate and/or calcium at these wells.

Elsewhere, selected wells demonstrate impacts from surface operations. BJ-GW11-3A/B show seasonally variable chloride which has been attributed to winter salt application near the wash bay. The only other wells showing clear influence of the mine are BJ-GW18-23A/B which intercept shallower groundwater flowpaths from the CWP.

Overall, groundwater quality data support conclusions from the water level data, *i.e.*, that the mine acts as a groundwater sink with groundwater flowpaths towards the mine.

2.8 Mine Infrastructure

Prior to construction of the Brucejack Mine in 2015, various operators explored the area beginning in 1980. Between 1986 and 1991, the Granduc Newcana Joint Venture, with Newhawk as operator, opened approximately 5,300 m of exploratory development in the West Zone. Drafted extents of the historic West Zone workings were provided by Pretium for incorporation into the groundwater model.

The 2015 to 2018 as-built mine information, which formed the basis of the 2020 groundwater model calibration (Lorax, 2020b), was provided on a monthly timestep. Examination of the plan revealed that individual stopes take on average 17 days to mine and remain open for approximately 10 days before they are backfilled over a few days. The 2019 to 2021 as-built mine plan, used in the validation of the groundwater model, was provided as an annual snapshot. Development extents at the end of 2018 (*i.e.*, the end of calibration period) and 2021 (*i.e.*, the end of validation period) are compared in Figure 2-10 and Table 2-8.

The future progression of the 4950 tpd mine plan was provided on a monthly timestep. The mine plan follows a 3800 tpd milling rate until 2024 and then increases throughput to 4950 tpd until the end of operations in December 2029. Development extents at end of the 4950 tpd mine life (2029) and 3800 tpd mine life (2032) are compared in Figure 2-11 and Table 2-8. Differences between the 3800 tpd and 4950 tpd end of mine extents include the following:

- The VOK extends 30 m deeper and ~175 m to the northeast on account of mining of extension areas of the Brucejack mineralization (circled area in Figure 2-11);
- Exploration developments are new and extend farther east, west and south than previously defined developments; and,
- A tunnel is advanced north of Brucejack Creek to establish a vent raise with surface elevation of 1392 masl.

Table 2-8:
Extent of Brucejack mine underground workings.

Mine Area	End of 2018	End of 2021	End of Mine[1] (3800 tpd)	End of Mine[2] (4950 tpd)
VOK				
Max Elevation (masl)	1480	1480	1535	1535
Min Elevation (masl)	1087	1015	990	960
West Zone				
Max Elevation (masl)	1369	1369	1385	1385
Min Elevation (masl)	1154	1154	1040	1040

Notes:
1. As simulated in 2020 groundwater model for a 3800 tpd mine plan (Lorax, 2020b).
2. End of current mining extents simulated in 4950 tpd groundwater model.

2.9 Conceptual Model For Groundwater Flow

2.9.1 Baseline

The Brucejack Mine is located in an area of pronounced topographic relief which experiences abundant precipitation. The topographic relief drives orographic gradients in precipitation, temperature and snowmelt. Nearby mountain peaks north of the WRSTF approach 2380 masl while ground falls precipitously to the west of the mine where Brucejack Creek meets the Sulphurets Glacier (elevation 1050 masl) (Figure 2-12). The WRTSF has an approximate elevation of 1364.5 masl.

Groundwater levels generally follow topography with steep horizontal hydraulic gradients. Groundwater seeps have been observed at site around the mine property. On a regional scale, groundwater flows westward following the trace of Brucejack Creek towards Sulphurets Glacier (Figure 2-12). A conceptual cross-section of groundwater flow diagram during the baseline period is shown Figure 2-14, with the orientation of the cross-section denoted in Figure 2-13.

Recharge to the groundwater system is via infiltration of precipitation, snowmelt and glacial meltwater. Seepage losses from lakes and creeks may also occur. Recharge via glacial meltwater is not well constrained but is inferred to operate all year round, while infiltration of rainfall and snowmelt is inferred to occur primarily between May and October. The seasonal pattern of recharge is evidenced in well hydrographs that fluctuate several to tens of meters throughout the year.

The Brucejack groundwater system resides largely within the bedrock aquifer. Unconsolidated materials (glacial till or colluvium) are thin and discontinuous throughout the site, particularly in the VOK deposit area (Figure 2-13). Overall, site data suggest bedrock hydraulic conductivity decreases with depth and does not appear to be correlated to lithology. The presence of larger scale faults such as the Brucejack Fault, Rainy Fault and Bruce Fault (Figure 2-13, Figure 2-14) are visualized as enhanced permeability structures that may act as preferential pathways for groundwater flow. Completion of the mine's potable water supply well in the Brucejack Fault supports this assertion (Figure 2-13).

Baseline mining features at the mine site (preceding Pretium ownership) included the flooded historic Newhawk exploration developments in the West Zone. The ramp extended about 260 m below ground surface, with the portal near Brucejack Creek, coincident with its current location, at an elevation of ~1365 masl. The historic portal was observed to passively drain towards Brucejack Creek.

Figure 2-12: Brucejack Mine seen from air, looking east. Green arrow denotes where Brucejack Creek meets the Sulphurets Glacier. Blue arrows denote general direction of groundwater flow under baseline conditions.

Figure 2-13: Approximate mine deposit areas, Bruce Fault, and Brucejack Fault as seen from air, looking south. Purple line denotes approximate section line location shown in Figure 2-14.

2.9.2 Operations

Pretium's dewatering of the flooded West Zone workings started in late 2011, and after a several months interruption, resumed in September 2012. In 2012, Pretium advanced a ramp from the West Zone towards the Valley of the Kings deposit, from which a 10,000 t bulk sample was extracted in 2013. Dewatering of the underground continued through 2015 to allow for underground fan drilling. Mine construction began in September 2015, with commercial production starting in July 2017. Under the 4950 tpd mine plan, mining will continue through to the end of 2029.

The underground mine is not a progressive geometry in that active mining areas alternate regularly. Stopes may be mined from a deeper level one month and then from a shallower level another month (or at the same time). Stopes themselves remain open for about a month prior to backfilling while developments (tunnels) remain open throughout mining. As a result, developments produce more water, especially those situated on the margins of mine.

A conceptual diagram of groundwater flow during operations is shown Figure 2-14, with the orientation of the cross-section denoted in Figure 2-13. Underground water is collected in a series of sumps and pumped to the water treatment plant. Some of this water is recirculated to the underground to service drills.

Since the inception of continuous mine dewatering in 2012, the dewatering record has followed a seasonal pattern whereby steeper hydraulic gradients result in higher groundwater inflows to the mine as a result of groundwater recharge from snowmelt and rainfall. Rapid upticks in underground dewatering rates occur after significant rainfall events, reflecting the quick flow through fractures (Figure 2-14). As an example, the Rainy Fault received its name for actively dripping into the workings which has been mitigated through grouting. Mine dewatering rates are expected to increase over life of mine as the mine envelope expands laterally and vertically.

Dewatering of the underground results in depressurization of the groundwater system from depth, creating or increasing downward gradients in nearby wells. A large drawdown cone has developed from current operations and will continue to develop through the end of mining in 2029 (Figure 2-14). The dewatering causes groundwater to flow towards the mine from areas that would otherwise discharge to the WRTSF or Brucejack Creek, including groundwater originating north of Brucejack Creek. This results in a modest reduction of baseflow in Brucejack Creek, although this would be offset to some degree by deposition of tailings and waste rock in the WRSTF. Brucejack Creek may itself recharge groundwater in its upper reaches on account of depressed water levels below the creek (Figure 2-14).

2.9.3 Closure Conditions

Following operations, the closure phase commences upon cessation of dewatering. The groundwater model simulates passive reflooding of the mine via two mechanisms: (i) groundwater inflows from surrounding areas and (ii) direct recharge over the mine area. A conceptual diagram of groundwater flow in the post-closure period is shown Figure 2-14.

At the beginning of closure, hydraulic gradients towards the mine are steepest, driving large groundwater inflows to the mine. As the water level in the mine recovers, the hydraulic gradients towards the mine decrease and ultimately reverse towards Brucejack Creek. This results in a recovery of baseflow in Brucejack Creek.

The water level in the mine will build up behind low permeability plugs installed at the portals and vent raise north of Brucejack Creek, ultimately reaching an equilibrium elevation where recharge to the mine will be matched by seepage out of the mine. The post-closure water table will be depressed compared to baseline conditions on account of the high connectivity of the underground developments (Figure 2-14). The open network of underground developments is envisioned as a large-scale sump. Negligible head loss is expected to occur through the developments as no backfilling developments is planned.

Contact water from the flooded mine is assumed to preferentially travel within the open developments towards the downgradient edge of the mine (Figure 2-14). From there, it is expected to travel preferentially in shallower, more permeable strata, towards Brucejack Creek. Surface seepage issuing from the portals may manifest as bypass around the plugs through the rock mass. Provided plugs are situated in competent ground, the bypass seepage is anticipated to be small.

PROJECT: **4950 tpd Groundwater Model Report**

TITLE: Conceptual Model of Groundwater Flow

PROJECT #: A624-4

FIGURE: 2-14

P:\@Drafting\Brucejack\Drafting Figures\Autocad Figures\Cross Sections\2022 Groundwater Report\Fig 2-14_CS-AA_20230206.dwg

3. Baseline Model

3.1 Overview

An updated simulation of baseline conditions has not been undertaken since the 2020 update (Lorax, 2020b) since bedrock hydraulic parameters and recharge rates have not been recalibrated in the 4950 tpd model. The baseline conceptual model, methods and results from the 2020 model update are described below.

3.2 Model Setup

3.2.1 Software Code

The update to the Brucejack groundwater model was undertaken in FEFLOW 7.2, a part of the MIKE software suite (DHI, 2022). The numerical model treats the hydrogeologic system as an equivalent porous medium. The water table elevation was arrived at while operating the model in 'phreatic' mode. The baseline model was run in steady-state mode reflecting equilibrium conditions.

3.2.2 Model Domain, Discretization

The groundwater model domain covers approximately 65 km^2 (Figure 3-1). The model boundary is constrained on the west margin by the centreline of the west arm of the Sulphurets Glacier. Downstream of the glaciers, Sulphurets Creek forms the model boundary.

The model domain is divided into 21 layers with each layer having uniform thickness over the domain except the bottom layer (Table 3-1). Model layer thickness ranges from 10 m to 30 m for depths including and beyond the extent of the planned workings. The model mesh is comprised of 114,358 elements per layer with node spacing ranging from approximately 15 m to 20 m in the mine area to 30 m to 40 m away from the mine area. In total, the model is comprised of 2,401,518 elements.

The top of Layer 1 corresponds to ground surface and is informed by a digital elevation model at a 25 m grid spacing. The ground surface was modified in areas covered by the Sulphurets Glacier to account for the thickness of ice. A 2016 radar survey of ice thickness along the Knipple Glacier indicated that the ice thickness is approximately 200 m at the portion of the Knipple Glacier closest to the Sulphurets Glacier. From this, a depth profile along the centerline of the Sulphurets glacier was created by assuming zero ice thickness at the bottom and top and 200 m thickness in the estimated accumulation zone. The centerline of the glacier was assumed to be the midpoint between the lateral moraines.

Note:
(-) fault is not explicitly simulated at this depth

3.2.3 Boundary Conditions

As shown in Figure 3-1, the baseline groundwater model was assigned the following boundary conditions:

- A no-flow boundary was assigned to the base of the model domain and along north, east, and south margins of the domain coincinding with the height of land defining the watershed boundary.
- Along the northwestern perimeter segment of the model domain, an unnamed tributary of the Sulphurets Creek was conceptualized as a gaining creek. Drain nodes were assigned to this creek in Layer 1 with reference elevation of 1.5 m below

topographic elevations. At depth, the creek valley functions conceptually as a no-flow symmetry boundary.

- Similarly, drain nodes were assigned in Layer 1 along Sulphurets Creek and the valley centreline of the west arm of Sulphurets Glacier, with the reference elevation 1.5 m below the ground surface. No-flow boundary conditions were assigned to the deep layers.
- A general head boundary or fluid-transfer boundary condition was assigned to Layer 1 beneath the WRTSF, with a reference head equivalent to the average elevation of the lake (1364.5 masl). To mimic the blinding of the lake bottom with sediments, the outflow conductance was assumed to be one order of magnititude higher than the inflow conductance. An outflow conductance of 1E-07 s^{-1} was determined through model calibration.
- To enable interaction between the underground workings and overlying water features, a general head boundary condition was applied to Layer 1 elements containing Upper Camp Creek Lake, Brucejack Creek, VOK Creek, and Camp Creek. The reference elevation for these features was set to 1.5 m less than the digital elevation model ground surface. A general head outflow conductance of 1E-07 s^{-1} was applied to VOK Creek, Camp Creek and Upper Camp Creek Lake. The conductance of Brucejack Creek was set to 1E-06 s^{-1}.
- Other high elevation creeks (*i.e.*, above 1500 masl) in the model domain (including Unnamed Creek) were also simulated with a general head boundary condition with an outflow conductance of 1E-07 s^{-1} and reference elevations equivalent to 1.5 m less than ground surface.
- Lower elevation creeks (*i.e.*, below 1500 masl) in the model domain were simulated as drain nodes with reference heads equivalent to 1.5 m less than ground surface.
- To simulate the presence of numerous groundwater seeps within the area, the zone around the Brucejack Mine approximately below 1500 masl was assigned a seepage face condition once the groundwater level is above the ground surface.

3.2.4 Discrete Features

The historic, flooded underground workings were simulated in FEFLOW using discrete features with flow through the tunnels governed by the Darcy equation with a hydraulic conductivity of 1.0 m/s. Tunnel dimensions of the historic workings are 5 m by 5 m.

3.2.5 Recharge

Recharge was applied as an areal flux to the top layer of the model in all areas except the WRTSF where zero recharge was applied. Outside of glaciated areas, the recharge rate was varied according to topography, reflecting the orographic gradient (Section 2.2). Figure 3-2 shows the distribution of recharge applied in the baseline model; values are expressed as a percentage of mean annual precipitation in Table 3-2. The recharge rates presented in Table 3-2 are the calibrated values that, in combination with the hydraulic conductivity values reported in Table 3-1, produced the best calibration to both groundwater levels and baseflows in the baseline model.

Table 3-2:
Mean annual precipitation and modeled groundwater recharge rates by elevation.

Elevation Band (masl)	MAP[1] (mm/yr)	Simulated	
		Calibrated Recharge (mm/yr)	% of MAP Applied as Recharge[2]
Glaciers (<900 to >1600)	(-)	80	(-)
<900	~1620	280	~17%
900 to 1400	1740	289	17%
1400 to 1700	1981	328	17%
>1700	2150	359	17%

Notes:
1. See discussion in Section 2.3.2.
2. Normalized to mean annual precipitation for the elevation band.

3.2.6 Hydrogeological Units and Parameters

The distribution of hydraulic conductivity values across Layer 1 is shown in Figure 3-3. Calibrated hydraulic conductivity values for bedrock are presented in Table 3-1 and compared to measured hydraulic conductivity values in Figure 3-4. Overburden is not explicitly simulated in the model; all bedrock and faults are simulated as isotropic.

Ultimately, it was found that the optimal calibration metrics could be achieved through a partitioning of the intact bedrock hydraulic conductivity into two zones based on elevation. Bedrock hydraulic conductivity in lower lying areas (<1450 masl) was simulated roughly 50% higher than bedrock hydraulic conductivity in upland areas (>1450 masl) to a depth of 380 m below ground surface. Hydraulic conductivity below 380 m is uniform across the model domain except in faulted areas. The model reflects a hydraulic conductivity trend that decreases with depth (Figure 3-3).

4,950 tpd Groundwater Model Update

TITLE: Layer 1 Hydraulic Conductivity

PROJECT #: A624-4

FIGURE: 3-3

P:\@Drafting\Brucejack\Drafting Figures\MXD\2022GW Report\Fig 3-5_Hydraulic Conductivity.mxd

Figure 3-4: Measured and modeled hydraulic conductivity (K) values.

The model simulates a fault along Brucejack Creek (Bruce Fault) as a highly permeable feature (hydraulic conductivity of 1E-05 m/s) extending to 320 m depth. The Brucejack Fault and Rainy Fault are assigned a hydraulic conductivity of 1E-06 m/s to a depth of 500 m. A small fault connecting BJ-GW11-1A/B to the West Zone workings is assigned the same parameters as for the Brucejack Fault and Rainy Fault.

The simulation of Brucejack and Rainy faults as permeable features is supported by multiple lines of evidence. Rapid upticks in dewatering rates after heavy rainfall events suggests that fracture flow does occur (Section 2.6). Seepage has also been specifically observed along the Rainy Fault (Section 2.4.2). The mine's potable drinking water well is completed in the Brucejack Fault north of Brucejack Creek (Figure 2-1), implying higher hydraulic conductivity associated with this feature.

3.3 Baseline Calibration

3.3.1 Overview

Bedrock hydraulic conductivity and recharge were varied in an iterative process to arrive at an improved calibration to baseline groundwater levels and Brucejack Creek baseflow as compared to the 2015 groundwater model (BGC, 2015). In the 2020 model, these parameter combinations were brought forward into the transient operations simulation (simulating years 2011 to 2018) to determine goodness of fit to observed water levels and

dewatering rates. The process was repeated until a reasonable calibration for both baseline and post-disturbance targets was achieved. The calibrated recharge and hydraulic conductivity distributions are presented in Figure 3-2 and Figure 3-3, respectively.

The update of the 2020 model to represent the 4950 tpd mine plan has not resulted in changes to the hydraulic conductivity or recharge distribution determined by the 2020 model. The baseline calibration results presented in the following sections are for the 2020 model and remain valid. The baseline simulation provided an acceptable water balance error (0.01% or 4.8E-06 m^3/s) for the BJ 1.74 catchment area which fully encompasses the mine (Table 3-3).

Table 3-3:
Water balance for BJ 1.74 catchment (2020 model).

Sources	Inflow (m^3/s)	Outflow (m^3/s)	Net Flow (m^3/s)
Dirichlet BC	0	0.058	0.058
General-Head BC	3.08E-05	0.021	0.021
Recharge	0.076	0	-0.076
Storage	0	0	0
Cross Basin Boundary	0.017	0.014	-0.003
Total	0.093	0.093	0

3.3.2 Water Level Elevations

A summary of water level calibration statistics is provided in Table 3-4. The calibrated model yields a normalized root mean squared error (NRMSE) of 7.0% and absolute residual mean of 8.64 m. Both values are an improvement on the original EA and permitting groundwater model metrics (Lorax, 2020b). Water level residuals are biased positive, with the model overpredicting water levels at 14 locations and underpredicting water levels at 6 locations.

Simulated versus observed water levels for individual monitoring wells are tabulated in Table 3-5. Water level residuals (simulated minus observed) are plotted versus elevation in Figure 3-6 with spatial distribution shown in Figure 3-7. The highest residuals (>25 m) are measured at deeper vibrating wire piezometer (VWP) locations SU-77 and DH-BGC12-21 in the VOK. The model, however, reasonably estimates water levels (residuals less than 10 m) at higher elevation datapoints in the VOK (BJ-GW11-5A/B, BJ-GW12-12A, SU-82S/D). The overestimation of water levels at SU-77 and DH-BGC-21 is not considered problematic and could be considered conservative for dewatering predictions.

Table 3-4:
Water level calibration metrics for the 2020 groundwater model.

Calibration Metrics	2020 FEFLOW Model
Number of Targets	20
Range of Observed Water Levels (m)	174
Residual Mean (m)	5.58
Absolute Residual Mean (m)	8.64
NRMSE (%)	7.0%
Correlation	y=1.0038x
Coefficient of Determination (R^2)	0.97

Note:
NRMSE – normalized root mean squared error

Table 3-6 compares observed and simulated vertical hydraulic gradients at nested well pairs. The 2020 model correctly predicts the direction of hydraulic gradients near the VOK at BJ-GW11-5A/B and at low-lying locations south of the WRTSF and Brucejack Creek. The model does not correctly simulate the direction of hydraulic gradients west of the Brucejack Fault (BJ-GW11-8A/B) and on the northern shore of the WRTSF (BJ-GW11-6A/BJ-GW12-6B). This is not considered problematic as these wells are more distant from mine infrastructure.

Table 3-6:

BJ-GW12-8A	1403.4	89.3	1385	0.121	1377.0	-0.036
BJ-GW12-8B	1403.3	47.9	1380		1378.5	

Notes:
1. Calculated or estimated annual average water level (BGC, 2015).
2. Upwards vertical gradient is positive.

The contoured baseline water table is shown in Figure 3-8 with water levels along cross-section A-A' presented in Figure 3-9. The water levels follow topography with the steepest horizontal gradients (~45%) driven by the topographic high north of the WRTSF (Figure 2-12). Groundwater draining the mine area flows northward towards Brucejack Creek and then deflects along VOK Creek following more subdued horizontal gradients (~6%). The model indicates that the lower portion of VOK Creek is gaining.

Simulated baseline water levels along Section A-A' indicate groundwater divides south of the VOK development and north of Brucejack Creek. Brucejack Creek is the main groundwater discharge zone along section. The deflection of equipotentials near the water table, particularly at BJ-GW12-12A/B indicates strong downward hydraulic gradients near

the future VOK development consistent with an area of groundwater recharge. Equipotentials become more vertical towards Brucejack Creek near the West Zone, then ultimately curve upwards (indicating upward hydraulic gradients) towards the groundwater discharge area defined by Brucejack Creek.

3.3.3 Baseflow

The 2020 groundwater model calibration utilized two baseline baseflow calibration targets: BJ 1.74 and BJ 3.10 (Figure 2-1, Table 3-7). The BJ 1.74 hydrometric station replaced the BJL-H1 station (used to calibrate the 2015 groundwater model) in 2014. The catchment area of BJL-H1 and BJ 1.74 stations is essentially identical which is reflected in a near identical baseflow targets (0.074 m^3/s at BJ 1.74 vs 0.073 m^3/s at BJL-H1).

The baseflow target at BJ 3.10, located at the outlet of the WRTSF, was introduced for the 2020 model update and was derived from the site-wide water balance model (Section 2.3.3). The 2020 model simulated 62 L/s baseflow at BJ 3.10 and 79 L/s baseflow at BJ 1.74 (Lorax, 2020b). These results nearly match targets and offer a significant improvement on baseflow simulated at BJL-H1 by the 2015 permitting model (BGC, 2015) (Table 3-7).

Table 3-7:
Comparison of observed and simulated baseflow at BJL-H1 and BJ 3.10

Baseflow Station	Target Flow (L/s)	2015 Simulated Flow[1] (L/s)	2020 Simulated Flow[2] (L/s)
BJ 1.74 (BJL-H1)	74 (73)	98	79
BJ 3.10	61	n/s	62

4. Operations Model (2011-2021)

4.1 Overview

The as-built operations groundwater model presented in the 2020 update was developed and calibrated using data collected between 2011 and 2018 (Lorax, 2020b). The 4950 tpd groundwater model builds on the 2020 model by implementing the as-built mine plan until the end of 2021 in a separate simulation. The calibrated parameters determined by the 2020 model remain unchanged, and thus data collected from 2019 through 2021 serve to validate the groundwater model.

4.2 Model Setup

4.2.1 Temporal Discretization

The calibration simulation was run on automatic timestep control from January 2011 to December 2018 for a total of 84 stress periods. The validation simulation run on automatic timestep control from January 2019 to December 2021 for a total of 36 stress periods.

4.2.2 Boundary Conditions

Boundary conditions from the baseline model were modified to simulate transient recharge and mine development over the 2011 to 2021 period.

4.2.2.1 Recharge

Monthly recharge values were applied according to the topographic zoning adopted in the baseline model (Figure 3-2). Recharge values for the 2011 to 2021 period were estimated from precipitation generated from ClimateBC (Wang *et al*, 2016) (Table 4-1) as the site weather station was relocated in 2014. The proportion of precipitation for a given year to the mean annual average (1944 to 2014) was derived and used to adjust the annual recharge rates employed in the baseline model (Table 3-2). Annual recharge values were distributed across the months for all years according to the distribution provided in Table 4-2. The monthly distribution of recharge was determined through the calibration process, but reasonably approximates the rain plus snowmelt distribution computed from the water balance model (Table 2-5).

Table 4-1:
Annual recharge values used in 2011 to 2021 models.

Year	Precipitation[1,2] (mm/yr)	Recharge (mm/yr)				
		Lowland (< 900 masl)	Low-Slope (900-1400 masl)	Mid-Slope (1400-1700 masl)	Upland (>1700 masl)	Glaciated Areas (variable elevation)
Average Year[3]	1950	280	289	328	359	80
2011	1860	267	276	313	342	76
2012	1676	238	246	279	305	68
2013	1696	238	246	279	305	68
2014	1913	280	289	328	359	80
2015	1984	280	289	328	359	80
2016	1770	255	263	298	327	73
2017	1611	232	240	272	298	66
2018	1329	190	197	223	244	54
2019	1890	271	280	318	348	78
2020	1956	281	290	329	360	80
2021	2143	308	318	360	395	88

Note:
1. Generated from ClimateBC (Wang *et al*, 2016) for an elevation of 1500 masl for years 2011-2018.
2. Measured at VOK station (elevation 1500 masl) for years 2019-2021.
3. Average of 1944 to 2014 values generated from ClimateBC with a scaling factor of approximately 0.75 for the elevation 1500 masl.

Table 4-2:
Monthly distribution of annual recharge.

	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
% of Annual Recharge	0	0	0	1%	12%	34%	19%	10%	10%	14%	0	0

4.2.2.2 Underground Workings

The underground workings were implemented in the model according to the as-built mine schedule provided by Pretium (Section 2.8). The 2011 to 2018 mine plan was provided in an excel file where a mine progression timeline was provided for stopes and development segments. This facilitated explicit representation of the monthly mine plan in the groundwater model between 2011 and 2018.

Developments (tunnels) and stopes were simulated by applying a drain boundary condition to the element with the elevation corresponding to the elevation of the tunnel or stope. Drain boundary conditions applied to developments remained active throughout the simulation while drains assigned to stopes were deactivated after one month to account for backfilling.

Simulation of the as-built mine plan over the 2019 to 2021 validation period required a different approach as only end of year annual snapshots were available. The as-built annual snapshots were compared to the previous 'future mine plan' that was implemented in the 2020 model for the same years with mine extents manually adjusted on the margins to approximate the as-built end of year snapshots. This was considered a reasonable approach as marginal areas of the mine have greater influence on dewatering rates rather than interior portions of the mine. As such, the mine plan implemented over the validation period represents a hybrid of the as-built mine and the 2020 mine plan. The 2020 3800 tpd mine plan was based on the plan presented in the 2019 Technical Report (Jones *et al.*, 2019).

4.2.3 Hydrogeological Units and Parameters

Calibrated specific yield and specific storage values used in the groundwater model are provided in Table 4-3. Water level hydrographs are particularly sensitive to bedrock storage parameters and the extensive data record (Section 4.2.3) served as useful calibration targets for fine tuning of these parameters. Water levels measured at monitoring wells BJ-GW11-6A/B were particularly useful in this regard since they appeared unimpacted by mining operations and provided a transient baseline calibration target.

The specific yield of backfilled stopes was adjusted to reflect mine waste porosity. The specific yield of stopes backfilled with waste rock was assumed to be 0.15, while the specific yield of paste-filled stopes was set to be equivalent to that of surrounding bedrock.

Table 4-3:
Summary of bedrock storage values used in the calibrated 2020 groundwater model.

Unit	Depth Interval (m bgs)	Specific Yield (-)	Specific Storage (m^{-1})
Faults			
BJ Creek (Layer 1)	0-10	0.1	1E-04
BJ Creek (Layer 2 to Layer 12)	10-320	0.01	1E-05
BJ Fault and Rainy Fault	0-500	0.01	1E-05
Intact Bedrock			
Layer 1 - Layer 3	0-50	0.001	1E-06
Layer 4 - Layer 7	50-170	0.001	5E-07
Layer 8 - Layer 9	170-230	0.001	2E-07
Layer 10 - Layer 14	230-380	0.0005	2E-07
Layer 15 - Layer 21	>380	0.0005	1E-07

The hydraulic conductivity distribution utilized in the as-built model is provided in Table 3-1 with one slight adjustment. In places where developments/stopes cross the Rainy Fault, the hydraulic conductivity of the element(s) containing the fault was decreased to correspond to the hydraulic conductivity of surrounding bedrock. The intent of this adjustment was to simulate grouting of the Rainy Fault during mining. Ultimately the

simulations indicated that once the Rainy Fault had been crossed, subsequent crossings produced nominal amounts of water.

4.3 Model Calibration and Validation

The Brucejack groundwater model calibration/validation benefits from an extensive hydrogeological dataset comprised of ten years of dewatering data and a long-term, high resolution water level record collected from over 30 wells. The wells are broadly situated about the mine site and capture the influence of key hydraulic features (*i.e.*, the Brucejack Fault). The dynamic flow and water level records serve as a robust data set upon which model hydraulic parameters and boundary conditions can be assessed. In an iterative process, parameter combinations were trialed in both the baseline steady state and transient operations model to arrive at a calibration that satisfied all calibration targets. The transient calibration attempted to reproduce some of these key features of the system response, without introducing unnecessary complexity.

4.3.1 Underground Dewatering Rates

Simulated dewatering rates until the end of 2021 are shown in Figure 4-1 and tabulated in Appendix D. While the 2020 groundwater model simulated underground dewatering over the 2011 to 2018 period, the calibration effort primarily focussed on the 2015 to 2018 period during which active mining occurred. The model reasonably simulates observed underground dewatering rates and captures intra-annual variability in flows (Figure 4-1).

Over the 2019 to 2021 validation period, the 4950 tpd model reasonably simulates peak underground dewatering rates but overshoots annual minima by 450 m^3/d to 900 m^3/d. From the discussion presented in Section 2.6, current observed dewatering rates are anticipated to underestimate actual rates by ~130 m^3/d on account of ventilation water losses, therefore the gap between simulated and observed dewatering rates could be decreased by ~130 m^3/d. The overprediction of low-flow period dewatering rates is flagged for further study in future updates of the groundwater model.

Measured and simulated cumulative dewatering volumes from January 2015 through December 2021 are shown in Figure 4-2. Over the calibration period (2015 to 2018), the model overpredicts cumulative dewatered volumes by about 3% (1.89 Mm^3 vs 1.84 Mm^3). Over the calibration and validation period (2015 to 2021), the model overpredicts cumulative dewatered volumes by about 13% (3.92 Mm^3 vs 3.47 Mm^3). Overall, the simulated dewatering rates are considered acceptable and reasonably conservative for estimating treatment requirements.

Figure 4-1: Simulated versus observed dewatering rates between 2012 and 2021.

Figure 4-2: Measured and predicted cumulative groundwater volume dewatered from the mine (2015 – 2021).

4.3.2 Water Level Elevations

A plan map of simulated drawdown at the end of 2021 is provided in Figure 4-3. The map is a composite of data from two layers in the model. Maximum drawdown from the VOK is simulated in Layer 19 (500 to 530 m bgs) of the model, while maximum drawdown from the West Zone is simulated in Layer 8 (170 to 200 m bgs) of the model. Approximately 70 m of drawdown is simulated in the West Zone, while upwards of 400 m of drawdown is simulated in the VOK.

Simulated end of 2021 water levels along Section A-A' are provided in Figure 4-4. In contrast to Figure 3-9, most groundwater flowpaths are towards the mine and not Brucejack Creek. Monitoring wells BJ-GW12-12A/B and BJ-GW12-9A/B are simulated to be dry with water levels several tens of meters below the bottom of the deeper well screen. This supports the theory that the observed water level in BJ-GW12-9B represents a locally perched water table.

Time series of simulated and observed water levels over the 2012 to 2021 period are shown in Figure 4-5 to Figure 4-7. Underlining of well IDs in the graph panes indicate the well was also calibrated in the baseline model (Chapter 3). Table 4-4 provides simulated and observed June 2021 drawdown while Table 4-5 provides simulated and observed vertical hydraulic gradients at nested well pairs.

The model generally simulates similar water level responses in shallow and deep wells as a result of the necessary simplification of the groundwater system. In well pairs where perched conditions or widely disparate water level behaviour occur, the model tends to reproduce one well's data better than the neighboring. Overall, the model simulates downward gradients at all well pairs, which is largely consistent with observed data (Table 4-5).

Wells situated close to the VOK (BJ-GW11-5A/B and BJ-GW12-12A) show good agreement between simulated and observed water levels over the calibration period (Table 4-4, Figure 4-5). These wells went dry before the validation period but simulated water levels at deeper wells established in 2018 (BJ-GW18-21A/B, -19A/B) are in good agreement with observed water level elevations.

Notes:
1. Negative values indicate downward gradient.

West of the VOK and west of the Brucejack Fault (Figure 4-3), the model simulates lower water levels than observed at BJ-GW18-20A/B, although annual variation appears reasonably matched. Ongoing monitoring at this well pair will elucidate whether the Brucejack Fault is limiting drawdown in this area. Far east of the VOK, simulated water levels are in good agreement with measured water levels at BJ-GW18-18A/B.

Situated between with West Zone and VOK, BJ-GW18-22A is the deepest monitoring well on site (380 m) (Figure 4-6). The model reasonably approximates observed water levels at this well, situated close to underground developments, but underestimates water levels in its nested counterpart (BJ-GW18-22B) screened nearly 300 m shallower.

The model reasonably approximates water level trends and seasonality at selected wells between the West Zone and Brucejack Fault (BJ-GW11-1B and BJ-GW12-11B) (Figure 4-6). The model performs better at these wells versus their associated well pair. West of the Brucejack Fault, the model reasonably approximates long-term trends (or lack thereof) at wells BJ-GW12-8A/B, BJ-GW14-13B and BJ-GW14-14A (Table 4-4).

Several wells east and north of the West Zone were available for calibration of the baseline and operations period model phases (left hand side of Figure 4-7). BJ-GW12-6B and BJ-GW11-6A, north of Brucejack Creek at the outlet of the WRTSF, are background wells which have demonstrated little response to mining (Table 4-4). These wells served as particularly useful targets for calibrating bedrock storage parameters up to 100 m depth. Seasonal fluctuations and absolute water level elevations are faithfully reproduced by the model at this well pair.

Immediately east of the West Zone, the model closely simulated water levels at BJ-GW11-3A until the end of 2019 but diverged significantly thereafter. At the shallow well BJ-GW11-3B, the model overpredicts drawdown and seasonal fluctuations. At nearby well pair BJ-GW18-17A/B, the model reasonably simulates water levels in shallower bedrock (~75 m deep at 17B) but overestimates water levels in deeper bedrock (~148 m deep at 17A). The overestimation of drawdown at one well (BJ-GW11-3A/B) versus the underestimation of drawdown at the other (BJ-GW18-17A) suggests that there may be a structural feature influencing water levels in this area which has not been included in the groundwater model. Pretium geologists have identified a potential fault in this area which may be considered in the next update of the groundwater model pending further characterization work.

4.3.3 Calibration/Validation Summary

In summary, the groundwater model has benefitted from a long-term and dynamic water level and dewatering record which has facilitated calibration of bedrock hydraulic

conductivity, bedrock storage properties and recharge. The model necessarily simplifies the groundwater system but reasonably simulates seasonal water level and underground dewatering rate fluctuations, long-term water level trends and broad spatial trends in water level data. Good performance of the model against observed water level data collected since 2018, particularly at locations where water level data did not exist previously, further enhances model credibility. The model is well positioned to assess monthly average dewatering rates during the open water season but tends to overestimate winter low flows.

Winter low flows and influence of potential structures east of the West Zone are earmarked for further consideration during future model updates. Continued daily monitoring of underground dewatering rates and continuous monitoring of groundwater levels as prescribed by the mine's monitoring programs will be sufficient to inform future model updates. Overall, the groundwater model is well positioned to inform groundwater management at the mine site.

5. Future Operations (2022-2029)

5.1 Overview

The future operations period has been updated in the 4950 tpd model. The mine plan follows a 3800 tpd milling rate until January 2024 and then increases throughput to 4950 tpd until the end of operations in December 2029. Where appropriate, results have been compared to the 2020 model (Lorax, 2020b) for context.

5.2 Model Setup

5.2.1 Temporal Discretization

The future operations model was run on automatic timestep control from January 2022 through the end of December 2029 for a total of 96 stress periods. Mining itself is projected to end in December 2029.

5.2.2 Boundary Conditions

5.2.2.1 Recharge

An 'average climate' recharge time series was implemented in the future operations groundwater model. The recharge values implemented in the groundwater model correspond to the first line, or "Average Year," of Table 4-1 and were distributed across the months according to Table 4-2. This time series was repeated over the eight year duration of future operations.

5.2.2.2 Underground Workings

The underground workings were implemented in the future operations model according to the mine schedule provided by Pretium (Section 2.7). Figure 2-11 shows the full end of mine extents. Developments and stopes were simulated as described in Section 4.2.2. Developments are kept open once explored and simulated as drains for the duration of mining. Drains simulating mining stopes are turned off after one month to account for backfilling.

5.2.3 Hydrogeological Units and Parameters

The hydraulic parameters utilized in the 2011-2021 simulations were applied to the future operations model with no adjustments.

5.3 Model Predictions

5.3.1 Underground Dewatering Rates

Underground dewatering rates predicted by the 4950 tpd model are compared to the 2020 model results in Figure 5-1 with cumulative dewatered volumes from January 2022 to end of mine presented in Figure 5-2 and tabulated in Appendix D. The 2020 groundwater model simulated the 3800 tpd mine dewatering period ending in December 2032 (Lorax, 2020b).

Predicted dewatering rates stabilize over the last three years of mine life (2027 to 2029), ranging annually between 2,600 m^3/d and 4,300 m^3/d (30 L/s to 50 L/s) (Figure 5-1). The 4950 tpd rates are marginally higher (by about 2 L/s) in the low flow period (April) than those predicted for the 3800 tpd mine plan simulated in the 2020 model (Lorax, 2020b). This increase in minimum flows arises from the differences in mine plans discussed in Section 2.8. Simulated peak monthly flow rates during the open water season are similar between the two mine plans.

The cumulative inflow to the 4950 tpd mine is 10% higher than the 3800 tpd model over the period of 2022 to 2029 but, overall, 15% lower than the 3800 tpd mine through 2032 (Figure 5-2). Essentially, the 4950 tpd mining rate results in less groundwater abstraction over the life of mine than the 3800 tpd mine plan due to a shorter mine life.

Figure 5-1: Simulated future underground dewatering rates for 3800 tpd and 4950 tpd groundwater models.

Figure 5-2: Cumulative underground dewatering rates for 3800 tpd and 4950 tpd groundwater models (January 2022 to end of mine).

5.3.2 Water Level Elevations

Figure 5-2 through Figure 5-5 illustrate January 2012 to December 2030 simulated groundwater elevations for the 4950 tpd mine plan. Time series of annual average drawdown, computed from simulated 2011 water levels, are provided in Appendix E with end of mine drawdown summarized in Table 5-1. Overall, predicted drawdown at the end of mine life for the 4950 tpd mine plan (year 2029) exceeds that of the 3800 tpd mine plan (year 2032) at all wells by 15 m on average.

Water levels in wells surrounding the VOK have already experienced significant drawdown from the existing mine (Section 4.3.2, Figure 5-3). Several wells experience a noticeable increase in drawdown around 2025 (BJ-GW18-21A/B, BJ-GW18-19A/B, BJ-GW18-18A) that is attributed to advancement of exploration developments east, south and west of the VOK between 2024 and 2026 (see Figure 2-11). Steadily decreasing water levels are also predicted at BJ-GW18-20A/B.

Most wells flanking the West Zone are simulated to experience marked water level decline starting in 2022 due to expansion and deepening of the West Zone (Figure 5-4 and Figure 5-5). The rapid decline is most noticeable in wells immediately adjacent to the West Zone (BJ-GW11-1A/B, BJ-GW11-3A/B), where water levels decline on the order of 80 m between 2021 and 2029 (Table 5-1). Water levels at BJ-GW18-22A are predicted to drop

over 150 m in the next several years due to expansion of the West Zone and VOK (Table 5-1, Figure 5-5). Mining of the extension areas of the Brucejack mineralization (Figure 2-11), which was not simulated in the 2020 model, produces significantly more drawdown at BJ-GW-18-22A in the 4950 tpd mine plan than in the 3800 tpd mine plan.

Drawdown from West Zone development also extends father afield, materializing in >50 m drawdown in wells west of the Brucejack Fault (BJ-GW12-8A/B, BJGW14-13A, BJ-GW14-14A) (Figure 5-4, Table 5-1) with lesser amount of drawdown (<20 m) experienced north of Brucejack Creek at BJ-GW11-6A/BJ-GW12-6B (Figure 5-5).

Table 5-1:
Simulated drawdown at end of mine for 4950 tpd and 3800 tpd models.

BJ-GW18-22A	1069.0	91	260	193
BJ-GW18-22B	1358.7	80	142	122

Notes:
1. Computed from simulated June 2011 water levels.
2. Computed from annual average water levels simulated for 2011 and end of mine year for 4950 tpd and 3800 tpd models.

A plan map of maximum drawdown at the end of mine is shown in Figure 5-6. The map is a composite of data from two layers in the model. Maximum drawdown from the VOK is simulated in Layer 20 (530 to 560 m bgs) of the model, while maximum drawdown from the West Zone is simulated in Layer 14 (350 to 380 m bgs) of the model. Maximum drawdown at the end of mine life exceeds 425 m in the VOK and 300 m in the West Zone.

Simulated baseline and end of operations water levels along Section A-A' are shown in Figure 5-7. Groundwater draining the area north of Brucejack Creek largely reports to the West Zone while the VOK continues to capture groundwater south of the mine. This is demonstrated in the backward particle tracks shown on Figure 5-6 which trace the origin of water arriving in the underground. Groundwater drawn from farther afield towards the VOK and West Zone tends to flow along the north and south extensions of the Brucejack Fault.

Figure 5-3: Simulated and observed groundwater level hydrographs near the VOK (2012-2029). Underlined well ID indicates location was calibrated in the baseline model.

Figure 5-4: Simulated and observed groundwater level hydrographs west of the West Zone (2012-2029). Underlined well ID indicates location was calibrated in baseline model.

Figure 5-5: Simulated and observed groundwater level hydrographs east and north of the West Zone (2012-2029). Underlined well ID indicates location was calibrated in baseline model.

5.3.3 Baseflow

Mine dewatering diverts groundwater to the underground that would otherwise report to surface drainages and the WRTSF. The result is a modest reduction of baseflow in Brucejack Creek (Figure 5-8, Appendix F). The predicted baseflow reductions at BJ 1.74 and BJ 2.62 do not consider any increase in flow in Brucejack Creek that results from displacement of water in the WRTSF from waste rock and tailings deposition. By the end of operations in 2029, baseflow is predicted to decrease by approximately 7 L/s or 12% at BJ 3.10. At BJ 1.74, baseflow is predicted to decrease by 20 L/s or 25%. Predicted baseflow reductions are similar for both 4950 tpd and 3800 tpd models. The permitting groundwater model predicted comparable end of mine baseflow losses of 21% at BJL-H1, immediately downgradient of BJ 1.74 (BGC, 2015).

At the end of operations, the model simulates average annual seepage from the WRTSF towards the underground on the order of 96 m^3/d (1 L/s) with peak seasonal losses of 212 m^3/d (1.5 L/s) experienced in April (Figure 5-9). For reference, baseflow to the WRTSF under baseline conditions is simulated to be 5,360 m^3/d. At the end of operations, the simulated baseflow to the WRTSF is 4,620 m^3/d. Noting that this seepage loss to the underground working zone will then be dewatered and diverted back to the WRTSF, it is reasonable to conclude that the total water balance of the WRTSF associated with this seepage loss will not be impacted.

Figure 5-8: Simulated baseflow at BJ 3.10 and BJ 1.74 (2019-2040).

Figure 5-9: Simulated seepage losses from WRTSF to the mine.

6. Closure and Post-Closure

6.1 Overview

The closure period simulations have been updated for the 4950 tpd mine plan with mine reflooding starting in January 2030. Portal plugs will be installed at the West Zone and VOK portals and in a vent raise daylighting north of Brucejack Creek, to allow groundwater to recover above the portal elevations.

The groundwater model simulates flooding of the mine via two mechanisms: (i) groundwater inflows from surrounding areas and (ii) direct recharge over the mine area. Assisted flooding to the mine via BJ 3.10 reclaim is not simulated in the groundwater model, rather it is handled in the water balance and water quality models (Lorax, 2023a,b). Therefore, the results presented below represent natural recovery of the groundwater system and do not necessarily reflect the currently preferred closure option for the underground.

6.2 Model Setup

Mine closure was simulated in two phases: closure and post-closure. The closure phase covers the period of active mine reflooding as the groundwater system recovers to a new equilibrium. The post-closure phase simulates the equilibrium condition where the mine has reflooded to its ultimate elevation and the system responds to seasonal recharge. The objectives of the closure and post-closure simulations were as follows:

- To estimate the underground flooding time under passive conditions;
- To predict changes to the groundwater flow system (*i.e.,* groundwater elevations and flow) during flooding and after equilibration of the groundwater system; and
- To estimate groundwater discharge to surface water receptors in post-closure.

6.2.1 Temporal Discretization

As stated above, closure of Brucejack Mine was simulated in two groundwater modeling phases. In the closure phase, mine reflooding was simulated in a series of steady-state model runs to simulate inflow to the mine at different prescribed mine pool elevations. This produced an inflow rate versus mine pool elevation curve which was used in tandem with the mine volume elevation curve to compute a reflooding time.

The post-closure phase was simulated as a transient run lasting five years. The starting heads for this simulation were imported from the steady-state model where the head in the mine pool was near equilibrium elevation.

6.2.2 Boundary Conditions and Discrete Features

6.2.2.1 Recharge

The steady state models used to estimate mine reflooding time used the average annual recharge values described in Section 3.2.3. The transient mine reflooding simulation simulating post-closure recovery utilized the average annual recharge distribution described in Section 5.2.2.

6.2.2.2 Underground Workings

Drain nodes employed in the underground for operation phases were removed during closure. Groundwater flow within tunnels at closure was simulated using discrete features governed by the Darcy flow equation. To conservatively simulate good connectivity of the mine developments and ensure a flat-water level within the mine zone, the hydraulic conductivity of the discrete features was assumed to be 1 m/s. As most developments (including ramps, declines, and level crosscuts) have cross-section dimensions of 5 m by 5 m, the cross-sectional area of the discrete feature was set to 25 m^2.

6.2.2.3 Hydrogeological Units and Parameters

The groundwater model assumes that mine portals and the vent raise north of Brucejack Creek will be plugged at closure. Plugs were simulated using a hydraulic conductivity of 1E-08 m/s with a thickness of approximately 10 m, equivalent to the top layer thickness of the single element to which they were applied. The elevations of the West Zone and VOK portals are approximately 1365 masl and 1408 masl, respectively. The surface elevation of the currently proposed vent raise north of Brucejack Creek is 1392 masl.

No other changes to hydraulic parameters (hydraulic conductivity, specific storage, specific yield) were applied in the closure models.

6.3 Model Predictions

6.3.1 Natural Reflooding Time and Volumetric Fluxes

Groundwater flows to and from the mine under natural reflooding conditions are compared to the flooded elevation in the mine (VOK) in Figure 6-1. Results for both the 4950 tpd mine plan and 2020 Update (3800 tpd mine plan) are presented. For both mine plans, the initial flooding rates are high on account of the large hydraulic gradient between the mine void and upgradient areas. As the water level recovers in the mine, the hydraulic gradient towards the mine decreases, causing inflow rates to decline.

As the water level in the mine reaches approximately 1355 masl, hydraulic gradients start to reverse in the West Zone area causing mine contact water to flow towards Brucejack Creek. For the 4950 tpd mine plan, this happens about 17 months after the onset of

reflooding. In the 3800 tpd mine plan, gradient reversal occurred around 21 months after the onset of reflooding (Figure 6-1). Groundwater fluxes to and from the mine at closure are tabulated in Appendix G.

The flooded mine reaches an equilibrium where mine inflow equals mine outflow around 24 months after onset of flooding, several months faster than what was predicted for the 3800 tpd mine plan (Lorax, 2020b). The equilibrium contact water flux issuing from the 4950 tpd mine plan varies seasonally between 10.4 L/s and 22.9 L/s, averaging 14.9 L/s annually. This is 4.7 L/s higher than what was predicted by the 3800 tpd model (Lorax, 2020b). The increase in contact water flux arises from an overall larger mine excavation arising from development of extension areas of the Brucejack mineralization and advancement of the vent raise north of Brucejack Creek and exploration developments (Figure 2-11).

Figure 6-1: Simulated inflow to, outflow from, and water level in the mine during closure for 4950 tpd and 3800 tpd models.

6.3.2 Travel Time

The travel time from West Zone to Brucejack Creek is on the order of two days to one week, as estimated from particle-tracking modeling. Given the high connectivity simulated for the flooded mine zone and the close proximity of the West Zone to Brucejack Creek, it

is reasonable and conservative to assume a "zero" travel time for the mine contact water to Brucejack Creek for the purpose of water quality modeling (Lorax, 2023b).

Forward particle tracking (Figure 6-2) indicates that the majority of contact water from the flooded underground workings reports to a confined stretch along Brucejack Creek between BJ 2.62 and BJ 3.10, with some contact water reporting below BJ 2.62 and to the WRTSF itself. For the purpose of arriving at conservative water quality model predictions and thus an aggressive treatment strategy, an upper end value of 95% contact water flow reporting above 2.62 is assumed in the water quality model.

6.3.3 Groundwater Elevations

The equilibrium water level in the 4950 tpd mine is expected to vary seasonally between 1393 masl and 1407 masl, averaging 1401 masl. This is essentially equivalent to the equilibrium water level predicted for the 3800 tpd mine plan (Figure 6-1).

The simulated post-closure water table is shown in plan view in Figure 6-2 along with forward particle tracks from the mine area. The simulated post-closure water table along Section A-A' is shown in Figure 6-3. A map of post-closure drawdown is illustrated in Figure 6-4. The high connectivity of the underground developments at closure creates a flat water table within the mine footprint area. As a result, the horizontal hydraulic gradient through the mine footprint area is low, on the order of ~2.5%. Contact water generated within the VOK workings is simulated to flow primarily within the open underground tunnel network towards the West Zone.

The post-closure water table is over 100 m lower over the VOK footprint as compared to baseline conditions (Figure 6-3, Figure 6-4). Groundwater flowpaths towards Brucejack Creek re-establish in the post-closure period hence the trajectory of contact water forward particles towards Brucejack Creek (Figure 6-2).

The model predicts that the West Zone portal plug will potentially service up to 44 m of head. The model predicts annual average seepage through the plugged portal amounting to 20 m^3/day which varies seasonally between 10 m^3/day to 30 m^3/day.

6.3.4 Baseflow

Simulated baseflow at BJ 3.10 and BJ 1.74 through closure are presented for both 4950 tpd and 3800 tpd models in Figure 5-8 and Appendix F. The results are similar for both mine plan simulations. At both BJ 3.10 and BJ 1.74, baseflow is expected to return to within 5% of baseline levels within three years of the onset of mine reflooding. The original permitting model also predicted minimal (<5%) difference in baseflow at BJL-H1 (immediately below BJ 1.74) between baseline and closure periods. Therefore, findings of earlier effects assessment on surface water quantity in Brucejack Creek remain valid with respect to predicted changes in baseflow quantity.

7. Model Sensitivity and Uncertainty

7.1 Model Sensitivity

7.1.1 Introduction

A sensitivity analysis was performed on the 2020 3800 tpd groundwater model and was informed by an extensive sensitivity analysis performed on the 2015 permitting groundwater model (BGC, 2015; Lorax, 2020b). The 2020 model sensitivity analysis remains valid for the 4950 tpd groundwater model since the calibration has not been updated and the revised mine plan produces similar results as the 2020 model. The 2020 model sensitivity results are summarized here for completeness.

For reference, the 2020 model sensitivity runs are classified into four types (Table 7-1) after Brown (1996) as cited in Wels *et al.* (2012). Type IV parameters are the most problematic as they impact model predictions and are not constrained through model calibration.

Table 7-1:
Model sensitivity types (after Brown, 1996).

Change in Predicted Parameter		Change in Calibration	
	Effect	**Insignificant**	**Significant**
Change in Prediction Results	**Insignificant**	Type I	Type II
	Significant	Type IV	Type III

7.1.2 Methods

The 2020 model sensitivity analysis involved running parameter variations in steady state simulations of baseline and end of operations (2032) periods. Selected sensitivity runs were also carried forward into a steady-state simulation of post-closure conditions. Implications of parameter changes on mine pool elevation, mine flooding time, subsurface contact water fluxes to Brucejack Creek and plug leakage rates were evaluated. A threshold change of 15% relative to the calibrated case was used as the criterion for determining whether a change was considered “sensitive”. For sensitivity runs carried into post-closure, a change in mine pool elevation of 10 m or greater was considered sensitive.

7.1.3 Results

Table 7-2 summarizes the sensitivity analysis undertaken on the 2020 model. The first six runs explored changes in global hydraulic conductivity and recharge and combinations thereof. In general, these values were changed less broadly than in the original permitting

model (BGC, 2015) as a consequence of having a longer and dynamic calibration record to constrain parameter values. Other sensitivity analyses tested hydraulic conductivity of specific features (faults, portal plugs).

Sensitivity runs on global recharge and/or hydraulic conductivity (Runs 1 through 6, Table 7-2) were categorized as Type III, meaning both calibration results and predictions (operations or post-closure) were sensitive to parameter changes. Contact water fluxes and reflooding time were found to be reasonably insensitive to a two-fold increase in global hydraulic conductivity (Run 3) but were sensitive to a two-fold decrease in global hydraulic conductivity (Run 4). While the baseline water level targets do not support a two-fold change in global hydraulic conductivity values, it is useful to know if the model underestimates global hydraulic conductivity, it will not necessarily underestimate contact water fluxes to Brucejack Creek. If the model overpredicts global hydraulic conductivity, mine reflooding times may be longer than simulated, however, contact fluxes to Brucejack Creek would be smaller.

The hydraulic conductivity of faults (Figure 2-6) were tested in Runs 7 through 10 (Table 7-2). Run 7 increased the K of the Rainy and Brucejack faults ten-fold. This resulted in a deterioration of the water level calibration and had a significant impact on predictions (Type III). A ten-fold reduction in fault conductivity values (Run 8) impacted the water level calibration but did not impact predictions (Type II).

Two thrust faults in the mine area (VOK Main Thrust and Upper Thrust, Section 2.4.2) were not explicitly simulated in the 2020 model. Both increasing and decreasing the hydraulic conductivity of these features (Runs 9 and 10) did not impact calibration results nor predictions. These features are only intermittently, if at all, intersected by the mine workings, so the insensitivity of the model to these features is not surprising.

Several post-closure runs were conducted where the properties of the portal plugs were tested. In the absence of plugs (Run 14), average annual discharge from the West Zone portal to Brucejack Creek is simulated to be ~70% higher than the combined contact water flux and plug leakage of the base case model. The elevation of the mine pool in this scenario is limited by the spill point of the West Zone portal (1365 masl).

Table 7-2:
Sensitivity analysis on 2020 FEFLOW model.

Notes:

n/a = not applicable, n.c. = not computed

1. S.A. = sensitivity analysis
2. Sens. = sensitivity; SEN = sensitive parameter change with respect to calibration or prediction metrics (>15% difference from base case); INS = indicates an insensitive parameter change (<15% difference from base case). For mine pool elevation, a difference of >20 m from base case is considered sensitive.
3. End of operations steady-state model results.
4. Closure steady-state model results.
5. Sensitivity type classified as per Table 7-1.
6. Kb = hydraulic conductivity distribution from baseline model.
7. Rb = recharge rate from the calibrated baseline model.
8. Equivalent to 1 in 10 wet year.
9. Equivalent to 1 in 10 dry year.

Mine pool elevation, contact flux to Brucejack Creek and plug leakage are insensitive to plug hydraulic conductivity values that are less than or equal to 1E-06 m/s. Once the plug hydraulic conductivity increases to 1E-04 m/s, subsurface contact water fluxes decrease markedly, but are offset by large plug leakage rates. It is unlikely that an engineered plug would be constructed with a hydraulic conductivity of 1E-06 m/s or greater. In a review of design guidelines for permanent tunnel plugs, Lang (1999) indicates seepage should never occur through a plug or along the rock/concrete contact but will always occur to some extent through the surrounding rock mass. Lang (1999) indicates that seepage rates of less than 0.5 L/s measured 20 m downstream of a plug can be easily achieved where the hydraulic conductivity of the rock mass is less than 1E-07 m/s. Therefore, while a significant increase in plug K values constitutes a Type IV parameter, it is reasonable to assume that much better plug performance and lower leakage rates through and around the plug can be achieved at closure.

Overall, the 2020 sensitivity analysis supported the use of the parameter values calibrated during model development. The same holds true for the 4950 tpd model since updates to this version of the model essentially amount to an accelerated mine plan of similar spatial extent while employing the same parameters. Any required future re-calibration of the model is expected to require only small adjustments in hydraulic conductivity and/or recharge.

7.2 Model Uncertainty

The dewatering data collected between 2019 and 2021, which form the basis of the groundwater model validation, provide opportunity to assess uncertainty in model predictions going forward. Figure 7-1 focuses on this time period and includes percent differences between simulated and observed dewatering rates.

In examining the 2020 model predictions, which used average climate and the proposed mine plan after Jones *et al.* (2019), the model generally overpredicts flows over the 2019 to 2021 period. More specifically:

- The largest percent differences from observed values occur during the low flow period, typically in March or April. March and April flows are overpredicted by 90% on average.
- During the open water season (May through October) flow rates are overpredicted by 30% on average. During the highest flow months (June, July), the model overpredicts flows on average by 20%.
- The largest overprediction during the open water season (by 100%) occurred in May 2021. This was due do a delayed freshet where overnight temperatures stayed below zero essentially until June.

Note that the percent differences above do not consider ventilation losses that are presumed to occur on the order of 130 m^3/d (Section) and therefore are biased high.

Figure 7-1: Simulated and observed groundwater inflows (2019-2021).

The 4950 tpd model simulates the 2019-2021 period using an approximate as-built annual mine plan and actual climate patterns. Therefore, differences between simulated and observed flow rates are more strongly attributed to model parameterization (hydraulic parameters, recharge distribution) than to the mine plan. The 4950 tpd model still overestimates low flows, but more accurately estimates open water season flows than the 2020 model (Figure 7-1). More specifically:

- Over the May to October open water season, the model overpredicts flows by 10% on average. During the highest flow months the 4950 tpd model underpredicts flows by 10% in June, and overpredicts flows by 10% in July.
- During the lowest flow months (March and April), the 4950 tpd model overpredicts flows by 90%.

The above suggests that if the mine plan were to be closely followed and average climate experienced, measured winter low flow data would still be ~90% less that the simulated values but open water season flows would be well constrained. The overprediction of

winter low flow data is flagged for future study. Initial attempts to reconcile winter low flows by lowering bedrock storage values did not significantly improve predictions, therefore other avenues of investigation are flagged for consideration.

Overall, the assumptions underpinning the groundwater model are conservative, and likely to overpredict future dewatering rates. The combined uncertainty in model predictions for future operations arising from model parameterization and deviations from the proposed mine plan and average climate may lead to an overestimation of open water and low flow season flow dewatering rates of 30% and 90%, respectively. The conservativeness of the groundwater model is considered appropriate for the objectives it is seeking to fulfil (Section 1.2).

8. Conclusions and Recommendations

8.1 Conclusions

The Brucejack groundwater model has been updated in support of a proposed production increase from 3800 tpd to 4950 tpd. Prior to this, the 3800 tpd groundwater model was most recently updated in support of the 2020 Update (Lorax, 2020b in Pretium, 2020). Data collected between 2018 and 2021 were used to validate the 2020 groundwater model which was modified to reflect as-built mine progress and, subsequently, future mine progress proposed under the 4950 tpd mine plan. The main findings of the groundwater model presented herein are as follows:

- Over the calibration and validation periods (2011-2018 and 2019-2021, respectively), the groundwater model reasonably simulates temporal and spatial trends in groundwater levels. The model also reasonably simulates long-term trends and seasonal fluctuations in underground dewatering rates, although winter dewatering rates tend to be overpredicted on the order of 450 m^3/d to 900 m^3/d. The validation period data confirmed that simulated hydraulic parameters and recharge are appropriate and that model recalibration was not warranted.
- Predicted peak monthly average dewatering rates for future operations are expected to stabilize in the last three years of mining at ~4,300 m^3/d. This is similar to peak rates predicted by the 3800 tpd model. Low flow dewatering rates are predicted to stabilize around 2,600 m^3/d which is ~500 m^3/d higher than the 3800 tpd mine plan. However, since the increased production rate is associated with a shorter mine life, the cumulative dewatered volume from the mine is predicted to be 15% lower than that predicted for the 3800 tpd mine plan.
- Monitoring wells across the mine site are predicted to experience on average 15 m more drawdown by the end of mining in 2029 than what was predicted for the 3800 tpd model. This is attributed to differences in the 4950 tpd mine extents which include slightly deeper and broader mine workings in the VOK area; long exploration drifts extended west, south and east of the VOK; and a vent raise advanced north of Brucejack Creek.
- The groundwater model predicts that the 4950 tpd mine will passively reflood to its penultimate elevation in 24 months, in the absence of assisted flooding. This is several months quicker than the 3800 tpd mine plan. The ultimate water level elevation in the mine is simulated to vary between 1393 masl and 1407 masl, averaging 1401 masl on an annual basis, provided that plugs are installed at the

VOK and West Zone portals and in the vent raise daylighting north of Brucejack Creek. This is consistent with predictions for the 3800 tpd mine plan.

- Contact water fluxes generated from the flooded mine are simulated to range seasonally between 10.4 L/s and 22.9 L/s, averaging 14.9 L/s annually. This is 4.7 L/s higher than what was predicted by the 3800 tpd model and is attributed to expansion of the mine extents as listed in the third bullet. The majority of contact water reports to Brucejack Creek between BJ 2.62 and BJ 3.10, with some contact water reporting below BJ 2.62 and to the WRTSF itself. For the purpose of arriving at conservative water quality model predictions and thus an aggressive treatment strategy, an upper end value of 95% contact water flow reporting above BJ 2.62 is assumed in the water quality model.
- The model predicts a 25% reduction in baseflow in Brucejack Creek at station BJ 1.74 by the end of operations in 2029. Baseflow is expected to recover 4% above baseline levels within three years of mine closure. These changes in baseflow are similar to those predicted for the 3800 tpd mine plan and the original 2700 tpd mine plan permitted in 2015, noting that baseflow offsets arising from tailings and waste rock deposition in the WRTSF have not been considered in either the current or previous modelling assessments. Therefore, findings of earlier effects assessment on surface water quantity in Brucejack Creek remain valid with respect to predicted changes in baseflow quantity.
- Sensitivity analyses performed on the 3800 tpd model remain valid for the 4950 tpd model and indicate that most parameters that influence model predictions are constrained in the calibration process. It is anticipated that future updates to the groundwater model will likely be associated with localized parameter adjustments to improve the model accuracy.
- Overall, the assumptions underpinning the groundwater model are conservative, and likely to overpredict future dewatering rates. The combined uncertainty in model predictions for future operations arising from model parameterization and deviations from the proposed mine plan and average climate may lead to an overestimation of open water and low flow season flow dewatering rates of 30% and 90%, respectively.

8.2 Recommendations

The 4950 tpd groundwater model update has benefited from a comprehensive environmental monitoring program that includes daily record keeping of underground pumping and recirculation volumes, dedicated water level dataloggers at all active

monitoring wells, a well-maintained site weather station, and routine streamflow monitoring. Continued implementation of this monitoring program will be instrumental in future groundwater model validation.

It is recommended that future updates of the groundwater model include new faults which may impart non-trivial hydrogeological influence on the mine. For instance, inclusion of a newly identified fault skirting the eastern extents of the mine may improve calibration to observed water levels in wells east of the West Zone. Focus should also be placed on resolving disparity between simulated and observed winter dewatering rates.

Notes:

Az. = azimuth; m ah = metres along hole; v m bgs = vertical meters below ground; K = hydraulic conductivity

1. Drill hole coordinates and elevations for the DH- and MW-series holes provided by Pretium from professional surveys in NAD83 UTM Zone 9N, with the exception of DH-BGC12-20, DH-BGC12-21 and BJ-MW-14B which are from a handheld GPS.
2. Simplified geology based on groupings provided in main report. Logging conducted by BGC and/or Pretivm staff.

PRETIUM RESOURCES INC.

A member of the Newcrest Group of companies

Project: Brucejack
Project No.: 1008-004

DRILL HOLE # MW-BGC11-BJ-1A

Location: West Zone

NEW ID: BJ-GW11-1A
ID CHANGE 14 DEC 18

Co-ordinates (m): 426,280E - 6,258,840N
Ground Elevation (m): 1,385.72
Survey Method: Surveyed
Datum: UTM NAD 83 Zone 9
Stick Up (m): 0.57
Surface Completion: PVC Stick-Up

Drill Designation: Heliportable
Drilling Contractor: Matrix
Drill Method: Diamond
Core: HQ
Top of PVC Elevation (m): 1386.3
Cased To (m): 3

Start date: 30 Sep 11
Finish Date: 02 Oct 11
Final Depth (m): 102.7
Depth To Top Of Rock (m): 0.3
Logged by: Pretium
Reviewed by: BGC

DRILL HOLE # MW-BGC12-BJ-9A

Location: Brucejack

NEW ID: BJ-GW12-9A
ID CHANGE 14 DEC 18

Co-ordinates (m): 426,465E - 6,258,361N
Ground Elevation (m): 1,514.40
Survey Method: Surveyed
Datum: UTM NAD 83 Zone 9
Stick Up (m): 0.73
Surface Completion: PVC Stick-Up

Drill Designation: Heliportable
Drilling Contractor: Radius
Drill Method: Diamond
Core: PQ
Top of PVC Elevation (m): 1515.1
Cased To (m): 1.5

Start date: 01 Aug 12
Finish Date: 04 Aug 12
Final Depth (m): 80.0
Depth To Top Of Rock (m): 0.0
Logged by: DP/LL
Reviewed by: KSJ

Lithologic Description	Comments
PLAGIOCLASE-HORNBLENDE PORPHYRY (P1) Moderately homogeneous porphyry, <2% veining, sericite alteration of matrix and phenocrysts. Strong to very strong (R4-R5). Faint weathering (W1-W1.5)	Water Level Measured on 8/14/2012: 1456.17 masl
7.7 m: Shear, 5 mm thick.

Lithologic Description

GRAVEL (GP)
Coarse, some cobbles, some boulders, grey to white, iron staining.

PLAGIOCLASE-HORNBLENDE PORPHYRY (P1)
Contains pervasive sericite-chlorite alteration with phenocryst replacement. Multiple veinlets. Medium strong to strong (R3-R3.5). Faint to slight alteration (A1.5-A2).
2.8 m: Fault, 60 mm thick, broken rock.

7.3 m: Fault, 110 mm thick, broken rock.

8.1 m: Fault, 70 mm thick, broken rock.

12.9 - 23.5 m: Stockwork (H7) with minimal mineralization. Steep wall rock veinlets (oriented 50-90 degrees TCA).

23.5 - 53.8 m: Some sections of conglomerated porphyry.

28.4 m: Fault, 300 mm thick, broken rock.
28.8 m: Fault, 200 mm thick.

COORDINATES:	426118 E, 6258904 N	DRILL CONTRACTOR:	Hy-Tech Drilling	LOGGED BY:	JMC/DP
ELEVATION (m asl):	1362.49				
DATUM:	NAD 83 UTM ZONE 9N	DRILL METHOD:	Diamond-Triple Tube	REVIEWED BY:	DP/TC

DEPTH (m)	GRAPHIC LOG	GEOLOGICAL DESCRIPTION	PACKER TEST RESULTS	DRILLING NOTES	WELL CONSTRUCTION DETAILS	DEPTH (m)
0.0		Ground Surface				
5.0		VOLCANIC ROCK ; fine to medium grained porphyry latite flow with hornblende phenocrysts, sub-mm sericite carbonate replaced plagioclase feldspar and hornblende phenocrysts throughout, generally 5-12 % composition, volcanic flows are weakly phyllic altered, local intensities of altered phenocrysts do occur, commonly distal from weak-moderate phyllic alteration, phenocrysts follow preferential foliation (45 depth to core axis), which also could be a feature of flow characteristic.		Hole initially drilled to HQ diameter, then reamed to PQ diameter.		
10.0			Packer Test 1 9.4 - 13.9 m Invalid Test	At 11.8 m: Fault; infilled with fault gouge, grey, soft, complete loss of drilling fluid circulation. No drill fluid circulation between 11.8 m and 100.9 m (EOH).		
15.0				At 17.6 m: Fault; oxidation staining, many quartz and calcite intrusions.		
20.0			Packer Test 2 21.2 - 28.9 m K=1.0x10-6 m/s	Between 19.6 - 35 m: Highly fractured zone, oxidation staining, surfaces are red-brown.		
25.0						
30.0						
35.0						
40.0						
45.0				Between 48 - 49 m: Fault zone; heavily broken, some sand, average particle size 30 to 50 mm, some fault gouge, annealed fault.		
50.0						
55.0				Between 72 - 75 m: Highly fractured zone; most joints occur parallel to intrusions, 0.5 to 2 mm apperture At 96 m: Fault; clay infilling, grey, wet, soft.		
60.0			Packer Test 4 19.9 - 100.9 m K= 1.8 x 10-7 m/s			
65.0				NOTES: 1) Water was used as drilling fluid. 2) Drilling fluid circulation was lost between 12 m bgs and the EOH (101 m). 3) Water level at the end of drilling (before grouting in well completion) was 4.1 m bgs 4) The stickup for the PVC was measured at 0.6 m after the installation. 5) Flowing artesian conditions (approximately 1 gallon/min) were encountered after completion of the well installation. 6) Well installation completed using 3" (77 mm) dia. schedule 40 PVC; 020 slot schedule 40 PVC well screens. Enviroplug 1/4" pellets were used for the bentonite seal along with cement-bentonite grout. Grade 3 silica sand (1.6 mm to 2.0 mm) was used for the filter. 7) Geological descriptions provided by Pretivm geologists.		
70.0

FOR SOIL/ROCK DESCRIPTIONS ON BOREHOLE LOGS

Project: Brucejack 2018 Groundwater Monitoring Well Installation and Site Investigation

Project Number: 1008029

SOIL/ROCK SYMBOLS		
Overburden	Fill	Till
Fragmental volcanics [V12]	Porphyry [P1]	Conglomerate [S3-Poly]
Silicified con-glomerate [H8]	Sandstone/ arenite [S4-Vsf]	Mafic dyke [V6]

INSTRUMENT DETAILS SYMBOLS		
Grout	Cuttings / slough	Bentonite chips
Bentonite pellets	Sand	Standpipe screen in sand
Standpipe in bentonite	Standpipe in grout	

NOTES

1. Depths are along hole and relative to ground surface.

LIST OF ACRONYMS	
A	Alteration
K	Hydraulic conductivity
R	Strength grade
W	Weathering
RMR	Rock mass rating
RQD	Rock quality designation

SYMBOLS AND TERMS

FOR SOIL/ROCK DESCRIPTIONS ON BOREHOLE LOGS

Project: Brucejack 2018 Groundwater Monitoring Well Installation and Site Investigation Project Number: 1008029

WEATHERING/ALTERATION [1]		
GRADE	**Description**	**Field Identification**
A/W 1	Fresh and Unweathered	No visible sign of rock material weathering
A/W 1.5	Faintly Weathered	Discolouration on major discontinuity surfaces
A/W 2	Slightly Weathered or Altered	Discolouration indicated weathering of rock material and discontinuity surfaces. All rock material may be discoloured by weathering and may be weaker than in its fresh condition.
A/W 3	Moderately Weathered or Altered	Less than 50% of rock material decomposed and/or disintegrated to soil. Fresh/ discoloured rock present as a continuous framework or corestones.
A/W 4	Highly Weathered or Altered	More than 50% rock material is decomposed or disintegrated to soil. Fresh/Discoloured rock present as discontinuous framework or corestones.
A/W 5	Completely Weathered or Altered	All rock material decomposed and/or disintegrated to soil. Original mass structure still largely intact
A/W 6	Residual Soil	All rock material converted to soil; mass structure and material fabric destroyed.

Note: Weathering/alteration half grades can be assigned to indicate a transition zone.

STRENGTH/HARDNESS CLASSIFICATION FOR ROCK [1]		
GRADE	**Description**	**Field Identification**
R6	Extremely Strong	Specimen can only be chipped with flat end of geological hammer
R5	Very Strong	Specimen requires many blows of flat end of geological hammer to fracture
R4	Strong	Specimen requires more than one blow of flat end of geological hammer to fracture
R3	Medium Strong	Cannot be scraped or peeled with pocket knife; can be fractured with single firm blow of flat end of the geologic hammer
R2	Weak	Can be peeled with pocket knife with difficulty; shallow indentation made by firm blow with point of geological hammer
R1	Very Weak	Crumbles under firm blow with point of geological hammer; can be peeled by a pocket knife
R0	Extremely Weak	Indented by thumbnail

Note: Strength/hardness half grades can be assigned to indicate a transition zone.

JOINT CONDITION [2]	
Condition of Joints	**Rating**
Very rough surfaces. Not continuous. No separation. Hard joint wall rock.	25
Slightly rough surfaces. Separation <1mm. Hard joint wall rock.	20
Slightly rough surfaces. Separation <1mm. Soft joint wall rock.	12
Slickensided surfaces or gouge <5mm thick or joints open 1-5mm. Continuous joints.	6
Soft gouge >5mm thick or joints open >5mm. Continuous joints.	0

Core recovery $= \frac{1.40}{1.50} = 93\%$

Solid core recovery $= \frac{1.06}{1.50} = 71\%$

R Q D $= \frac{0.95}{1.50} = 63\%$

Fracture index $= \frac{8}{1.50} = 5.3$ /m run

If strength grade ≤ R1, do not include in RQD.

SYMBOLS AND TERMS

FOR SOIL/ROCK DESCRIPTIONS ON BOREHOLE LOGS

Project: Brucejack 2018 Groundwater Monitoring Well Installation and Site Investigation Project Number: 1008029

Texture [3]		
Term	**Particle Size**	**Examples**
Very Coarse	> 60 mm	Porphyritic
Coarse	2 - 60 mm	Breccia, Gneiss (measurable grains)
Medium	0.06 - 2 mm	Sandstone, Gabbro, Granite, Schist (visible grains)
Fine	0.002 - 0.06 mm	Tuff, Siltstone, Claystone, Mudstone, Basalt
Very Fine	< 0.002 mm	

Fabric	
Term	**Description**
Homogeneous/ Uniform	Equigranular or homogeneous grains
Bedded	Deposited in layers, can be sedimentary or volcaniclastic rocks
Foliated	Minerals are aligned due to shearing or metamorphism
Gneissic	Alternating layers of different colour or texture with mineral alignment and typically parts along layers
Porphyritic	Crystalline texture with bimodal grain size distribution, fine to medium grained groundmass with coarse to very coarse phenocrysts
Stockwork	Veins (typically quartz, calcite, or gypsum/anhydrite) make up greater than 10% of the rock mass, they may be aligned with foliation or irregularly oriented
Microfractured	Hairline fractures are the primary fabric of the rock, typically oriented in all directions and intersecting one another
Brecciated	Healed or welded angular clasts with matrix, may be matrix – or clast-supported

Depth (m)	GEOTECHNICAL DESCRIPTION, MAJOR DISCONTINUITIES, AND ADDITIONAL NOTES
0	FILL and OVERBURDEN (0.00 m to 1.12 m)
1.12	MAFIC DYKE [V6a] (1.12 m to 6.00 m) Green, aphanitic mafic dyke. Closely spaced discontinuities, slightly rough joint surfaces with moderately to highly weathered walls, very strong to extremely strong, slightly weathered. Jointing sometimes along quartz veins, with apertures 1-20 mm, commonly with red-brown-black oxidized joint surfaces and broken/crushed rock infill. Two joint sets, at approximately 30° and 70° to core axis. At 6.00 m: Contact between mafic dyke and fragmental volcanics has weak chill margins, is oxidized, and is at 25° to core axis.
6.00	FRAGMENTAL VOLCANICS [V12] (6.00 m to 75.00 m) Medium grey fragmental intermediate volcanic. Matrix is composed of ash to fine-grained volcanic groundmass with 2-5 mm sub-blocky plagioclase phenocrysts ranging from 2-10% throughout. Angular lapilli fragments of aphanitic to porphyritic volcanics 10-150 mm are prevalent. Moderate alignment of fragments and phenocrysts are observed. Weak pervasive quartz-sericite-pyrite alteration with weak calcite replacement of plagioclase phenocrysts. Rare quartz-calcite [Vn3] veins throughout as planar to undulatory vein sets. Widely to extremely widely spaced discontinuities, very rough joint surfaces with unweathered walls, very strong to extremely strong, fresh. Joints occasionally along veins, with apertures typically < 1 mm, often with calcite coatings, generally 20-30° to core axis. From 6.00 m to 10.72 m: Red-brown-black iron oxide staining on joint surfaces.

From 65.00 m to 76.76 m: Joint apertures 1-5 mm and infilled with silt and/or clay.

At 75.00 m: Contact between fragmental volcanics and porphyry is ambiguous.

PLAGIOCLASE-HORNBLENDE PORPHYRY [P1] (75.00 m to 142.68 m)
Medium grey porphyritic volcanics/intrusives. Predominantly composed of euhedral, clay-altered mafic (hornblende?) phenocrysts and subhedral, calcite-altered plagioclase phenocrysts ranging from 5-25% throughout a grey, fine-grained matrix. Weak alignment of phenocrysts. Occasional intermediate fragments. Weak, pervasive, quartz-sericite-pyrite alteration with weak calcite replacement of plagioclase phenocrysts. Rare quartz-calcite [Vn3] veins throughout as planar to undulatory vein sets.

Widely to extremely widely spaced discontinuities, slightly rough to very rough joint surfaces with unweathered walls, very strong to extremely strong, fresh.

Joints with apertures typically < 1 mm, sometimes with calcite or chlorite coatings.

At 142.68 m: Contact between porphyry and fragmental volcanics is weak to moderately sharp.

FRAGMENTAL VOLCANICS [V12] intruded by MAFIC DYKES [V6b] (142.68 m to 148.12 m)
Fragmental volcanics are medium grey and intermediate. Matrix is composed of ash to fine-grained volcanic groundmass with 2-5 mm sub-blocky plagioclase phenocrysts ranging from 2-10% throughout. Angular lapilli fragments of aphanitic to porphyritic volcanics 10-150 mm are prevalent. Weak pervasive quartz-sericite-pyrite alteration with weak calcite replacement of plagioclase phenocrysts. Mafic dykes are green, aphanitic, and intruded by strong quartz-calcite-chlorite [Vn4b] veining.

Moderately wide to wide discontinuity spacing, slightly rough to very rough joint surfaces with moderately weathered to unweathered walls, very strong to extremely strong, fresh to slightly weathered.

Packer Test 2: 145.12 m to 148.12 m, K ≥ 10^{-6} m/s.

At 146.62 m: Lost drilling fluid circulation.

From 146.62 m to 147.40 m: White quartz vein, coarse-grained, vuggy, closely to moderately spaced discontinuities, slightly weathered.

END OF HOLE at 148.12 m.

NOTES
1) Installed 60.3 mm outer diameter schedule 80 polyvinyl chloride standpipe piezometer with 0.020 in slot size screen from 147.72 m to 144.67 m.
2) Filter sand (10-20 mesh size) placed around screen zone from 148.12 m to 142.07 m.
3) Bentonite pellet seal (coated, 1/4") placed above screen zone from 142.07 m to 140.67 m.
4) Bottom of piezometer is capped with an 0.20 m polyvinyl chloride sump with a slip cap glued to the lower end of the sump.
5) Water level measured after piezometer installation on 4 July 2018 at 108.30 m bgs.

FILL and OVERBURDEN (0.00 m to 1.19 m)

FRAGMENTAL VOLCANICS [V12] (1.19 m to 69.28 m)
Medium grey fragmental intermediate volcanic. Matrix is comprised of ash to fine-grained volcanic groundmass with 2-5 mm sub-blocky plagioclase phenocrysts ranging from 2-10% throughout. Angular lapilli fragments of aphanitic to porphyritic volcanics 10-150 mm are prevalent. Weak pervasive quartz-sericite-pyrite alteration with weak calcite replacement of plagioclase phenocrysts. Veining is negligible <1% throughout. Rare quartz-calcite [Vn3] generations are observed throughout as planar to undulatory vein sets.

Widely to extremely widely spaced discontinuities, slightly to very rough joint surfaces with slightly weathered to unweathered walls, very strong to extremely strong, fresh.

Joints apertures typically < 1 mm, often with calcite coatings, sometimes with sand, silt, and/or clay infill, variable joint orientations.

From 1.19 m to 1.69 m: Green, aphanitic, mafic dyke [V6] that intrudes the fragmental volcanics.

From 1.19 m to 3.49 m: Moderately spaced discontinuities, slightly rough joint surfaces with highly weathered walls and separation 0-5 mm, strong to very strong, slightly weathered.

From 1.27 m to 14.30 m: Joint surfaces have iron oxide stainings.

At 2.53 m: Broken rock zone, 150 mm length, rock fragments are medium strong.

At 69.28 m: Contact between [V12] and [P1] is weakly developed.

PLAGIOCLASE-HORNBLENDE PORPHYRY [P1] (69.28 m to 105.49 m)
Medium grey porphyritic volcanic/intrusives. Predominantly comprised of euhedral, clay-altered mafic (hornblende?) phenocrysts and subhedral, calcite-altered plagioclase phenocrysts ranging from 5-25% throughout a grey, fine-grained matrix. Weak alignment of phenocrysts. Occasional intermediate fragments. Weak, pervasive, quartz-sericite-pyrite alteration with weak calcite replacement of plagioclase phenocrysts. Veining is negligible <1% throughout. Rare quartz-calcite [Vn3] generations are observed throughout as planar to undulatory vein sets.

Widely to extremely widely spaced discontinuities, slightly to very rough joint surfaces with slightly weathered to unweathered walls, very strong to extremely strong, fresh.

Joints apertures typically < 1 mm, often with calcite coatings, sometimes with sand, silt, and/or clay infill, generally 20-30° to core axis.

Packer Test 2: 71.49 m to 105.49 m, K ~ 9×10^{-8} m/s.

Packer Test 3: 74.49 m to 105.49 m, K ≤ 10^{-8} m/s.

Predominantly comprised of subhedral, calcite-altered plagioclase phenocrysts ranging from 5-25%, with minor specks of dark mafic phenocrysts throughout a green, fine-grained matrix. Occasional mafic fragments. Weak to strong pervasive quartz-sericite-pyrite alteration with moderate pervasive chlorite replacement. Interval of minor 2% quartz-calcite veining. Dominantly comprised of cuspate-lobate [Vn1a] and planar to brecciate grey-pink calcite [Vn3] veins. Lesser crosscutting [Vn4b] tension gash style veins and pyrite-rich [Vn0] veins. Moderately to widely spaced discontinuities, variably slightly to very rough joint surfaces with highly weathered to unweathered walls, strong to very strong, slightly weathered to fresh. Joint apertures typically < 1 mm, often with oxide staining on joint surfaces, sometimes with calcite or chlorite coatings, mostly oriented approximately 30° or 70° to core axis. From 1.03 m to 8.22 m: Slightly weathered, moderately spaced discontinuities, slightly rough joint surfaces with highly weathered walls and separation 0-5 mm.

PLAGIOCLASE-HORNBLENDE PORPHYRY [P1] (0.00 m to 196.89 m)
Light to dark green porphyritic volcanic/intrusive. Predominantly comprised of subhedral, sericite-altered plagioclase phenocrysts ranging from 5-25%, with minor specks of dark mafic phenocrysts throughout a green, fine-grained matrix. Weak alignment of phenocrysts. Rare mafic fragments. Moderate pervasive chlorite replacement with isolated intervals of strong pervasive quartz-sericite-pyrite alteration. Variable veining structures.

Variable rock mass and discontinuity properties detailed in specific intervals.

From 0.00 m to 7.00 m: Trace veining consisting of [Vn3] veinlets.

From 0.00 m to 13.88 m: Very close to moderately spaced discontinuities, slightly rough joint surfaces with slightly to highly weathered walls, medium strong to strong, slightly to moderately weathered. Discontinuities with variable apertures generally 1-5 mm with some larger broken rock zones, frequent iron oxide staining on joint surfaces, sometimes with calcite or chlorite coatings, primary joint orientation is approximately 30° to core axis.

From 7.00 m to 22.89 m: 3-5% veining consisting of predominantly mm and cm scale [Vn3] and [Vn1a]/[Vn1b] (some strong ankerite replacement in [Vn1]). Few [Vn4]. Common discontinuous [Vn1].

From 13.88 m to 47.92 m: Moderately to widely spaced discontinuities, slightly rough to very rough joint surfaces with slightly weathered to unweathered walls, very strong, fresh. Discontinuity apertures generally < 1 mm, commonly with calcite coatings, sometimes with iron oxide staining on joint surfaces, variable joint orientations.

From 18.43 m to 18.72 m: Zone of decreased discontinuity spacing, iron oxide staining, some crushed rock infill.

PLAGIOCLASE-HORNBLENDE PORPHYRY [P1] (0.00 m to 159.54 m)
Grey-green porphyritic unit with 2 mm feldspar laths. Both phenocrysts and groundmass have been altered to sericite. Chlorite and sericite alteration. Variable veining structures.

Widely to very widely spaced discontinuities, slightly to very rough joint surfaces with moderately weathered to unweathered walls, strong to extremely strong, fresh to slightly weathered.

Discontinuity apertures generally < 1 mm, sometimes with calcite and/or chlorite coatings, occasional trace sand or clay infill, primary joint orientations are 20-30° and 60-70° to core axis.

From 0.00 m to 8.29 m: Very close to close discontinuity spacing, slightly rough joint surfaces with slightly to highly weathered walls, medium strong to strong, slightly to moderately weathered. Discontinuities with apertures generally 1-5 mm, iron oxide staining on joint surfaces, sometimes with disintegrated rock (clay) infill, primary joint orientations are 30-40° to core axis.

From 0.00 m to 43.00 m: 1% planar [Vn1a] veins.

From 8.29 m to 18.95 m: Moderately spaced discontinuities, slightly rough joint surfaces with slightly weathered walls, medium strong to strong, slightly weathered to fresh. Discontinuities with apertures < 1 mm, iron oxide staining on joint surfaces, primary joint orientations are approximately 30° and 70° to core axis.

OVERBURDEN (0.00 m to 1.16 m)

PLAGIOCLASE-HORNBLENDE PORPHYRY [P1] (1.16 m to 100.00 m)
Light green volcanic intrusive. Quartz-feldspar phenocrysts less than 20 mm. Upper 18 m show oxidation with limonite along fracture surface. Mostly sericite-chlorite alteration. Galena-sphalerite-sulfide veins linked to oxidation zones in top of hole and strong sericite-chlorite alteration at approximately 63 and 84 m in moderate-high angle quartz-calcite veins. 5-7% quartz and quartz-calcite veining. Mostly comprised of high and shallow angle [Vn1a] veining and shallow-moderate [Vn3] veining. Late stage [Vn4] tension veining.

Widely to extremely widely spaced discontinuities, slightly to very rough joint surfaces with slightly to highly weathered walls, strong to very strong, fresh.

Discontinuity apertures generally < 1 mm, jointing often occurring along quartz-calcite veins, frequent calcite and chlorite coatings, primary joint orientation 60-70° to core axis.

From 1.16 m to 19.73 m: Mostly oxidized [Vn3] quartz-calcite veining at high angle to core axis. Minimal [Vn2] veining with galena and sphalerite at low angle to core axis.
Fracture-controlled quartz veining. Close to moderately spaced discontinuities, slightly rough joint surfaces with highly weathered walls and separation typically 1-5 mm, medium strong to strong, slightly to moderately weathered. Discontinuities commonly with iron oxide staining on joint surfaces, sometimes with crushed rock (sandy or clayey) infill, primary joint orientations approximately 30° and 60° to core axis.

At 7.08 m: Crushed/disintegrated rock zone, 60 mm length.

PLAGIOCLASE-HORNBLENDE PORPHYRY [P1] (100.00 m to 177.34 m)
Dark green matrix-supported porphyritic intermediate-mafic volcanic. Contains 2-3% chlorite-altered hornblende phenocrysts 1-5 mm wide and largely sub-angular. Beige-white sericite-altered feldspars make up 5-10% of phenocrysts, are 1-2 mm wide and rounded to sub-rounded. Phenocrysts sit in green chlorite-altered matrix but are distinct in colour. Rare 10-20 mm chlorite- and sericite-altered phenocrysts visible. Weak-moderate chlorite alteration throughout matrix and within hornblende phenocrysts. Sericite-replaced feldspars make up small percentage of interval. Epidote replacement of plagioclase phenocrysts. Weak veining (2-3%) containing mostly thin, planar to rarely disarticulated [Vn3] (2%), thicker (50-150 mm) [Vn4] containing chlorite along selvages and within vein, and rare [Vn1a] (10-20 mm thick and planar).

Widely to very widely spaced discontinuities, slightly to very rough joint surfaces with slightly to highly weathered walls, strong to very strong, fresh.

Discontinuity apertures < 1 mm, jointing sometimes along quartz-calcite veins, frequent calcite and chlorite coatings, variable joint orientations.

From 115.12 m to 118.90 m: Increased fracture frequency zone, joints cross-cutting quartz-calcite veins, with chlorite coatings on joint surfaces.

Packer Test 2: 115.84m to 118.54 m, K ~ 8×10^{-8} m/s.

Depth (m)	Instrumentation & Hole Completion Details	Geotechnical Description, Major Discontinuities, and Additional Notes
0		OVERBURDEN (0.00 m to 0.61 m)
0.61 – 20		PLAGIOCLASE-HORNBLENDE PORPHYRY [P1] (0.61 m to 120.34 m) Green porphyritic volcanic/intrusive. Predominantly comprised of subhedral, sericite-altered plagioclase phenocrysts ranging from 5-25%, with minor specks of dark mafic phenocrysts throughout a green, fine-grained matrix. Weak alignment of phenocrysts. Rare mafic fragments. Moderate pervasive chlorite replacement with isolated intervals of strong pervasive quartz-sericite-pyrite alteration. Moderate pervasive chlorite alteration throughout with strong sericite replacement of phenocrysts. Interval of moderate 4-5% quartz-calcite veining. Dominantly comprised of planar to undulatory [Vn1a] and grey-calcite [Vn3] veins typically oriented at a shallow angle to the core axis. Moderate [Vn4] tension gash style veins crosscut these veins and are oriented at a high angle to the core axis. Widely to very widely spaced discontinuities, slightly rough to very rough joint surfaces with variably highly weathered to unweathered walls, generally strong to very strong, fresh. Discontinuity apertures typically < 1 mm, frequently with calcite and/or chlorite coatings, primary joint orientation approximately 40° to core axis. From 0.61 m to 17.25 m: Strong fracture-controlled orange oxidation and earthy orange goethite/limonite replacement in veins. Strong pervasive quartz-sericite-pyrite alteration. Interval of strong 10% quartz-base metal sulfide veining in highly fractured and oxidized zone. Dominantly comprised of strongly mineralized and sheeted [Vn2] base metal sulfide veins that are marginal to faults. [Vn1a] and overprinting [Vn3] grey-calcite networks/stockworks that are often fracture controlled. Veins often display vuggy textures that are replaced by orange earthy iron oxides (goethite/limonite). Lesser [Vn4] veins. Close to moderately spaced discontinuities, slightly rough joint surfaces with slightly to highly weathered wall rock, strong, slightly weathered. Discontinuity apertures typically 1-10 mm, common iron oxide staining on joint surfaces, some broken and crushed rock infill in larger aperture discontinuities, some chlorite coatings, variable joint orientations. From 5.09 m to 6.22 m: Strongly developed fault zone characterized by strongly oxidized surfaces, iron oxide replacement and quartz-base metal sulfide veining. Subsidiary fracture networks are common. Sections 10-60 mm length of fault gouge (broken/crushed rock, clayey), oriented approximately 30° to core axis. From 17.25 m to 40.51 m: Moderately spaced discontinuities, slightly rough joint surfaces with slightly to highly weathered walls, strong, fresh. Discontinuity apertures approximately < 2 mm, frequent calcite and occasional chlorite coatings, occasional iron oxide staining on joint surfaces, variable joint orientations.

Depth (m)	GEOTECHNICAL DESCRIPTION, MAJOR DISCONTINUITIES, AND ADDITIONAL NOTES
0	TILL (0.00 m to 2.78 m) Silt and gravel, trace sand, trace clay, cobbles.
3	INTENSELY-SILICIFIED CONGLOMERATE [H8] (2.78 m to 9.06 m) Grey, strongly silicified interval. Ghosted textures suggest original rock type was [S3]. Closely spaced discontinuities, slightly rough joint surfaces with slightly to highly weathered walls, some larger apertures joints with gougey infills, extremely strong, slightly weathered. Discontinuity apertures generally 1-5 mm, some broken rock zones up to 200 mm long, iron oxide staining on joint surfaces, frequent crushed rock infill, primary joint orientations approximately 30° and 60° to core axis. From 2.78 m to 41.22 m: Overall 1-3% veining with local 1-2 m sections with elevated veining to 3-5%. Veining is predominantly 10-30 mm [Vn1a] veins with lesser [Vn1c] veins that are up to 200 mm, and rare brecciated [Vn1b] veins. Rare base metal sulfide [Vn2] veins. Weak base metal sulfide mineralization in select [Vn1] generation veins. Veins range from planar to weakly deformed with cuspate-lobate margins. At 3.28 m: Gougey fault with fairly planar contacts. At 4.89 m: Gougey (clayey) to rubbly (crushed rock) fault with irregular contacts, 170 mm length.
9.06	CONGLOMERATE [S3-Poly] (9.06 m to 29.55 m) Grey-green, matrix-supported conglomerate with sub-rounded to rounded coarse, granular to pebble sized clasts. Clasts are commonly strongly sericite altered. Moderately spaced discontinuities, slightly rough joint surfaces with slightly to highly weathered walls, very strong to extremely strong, fresh. Discontinuity apertures generally < 1 mm, frequent crushed rock (clayey) infill, primary joint orientation approximately 20-30° to core axis.

SANDSTONE/ARENITE [S4-Vsf] (41.22 m to 255.28 m)
Medium greenish-grey, massive, silty to coarse sand [S4-Vsf]. Rare < 1 m interbeds of [S3] as observed above. Occasional calcite-pyrite concretions. Some patches of high-temperature sericite alteration. Overall 1-3% veining with local 1-2 m sections with elevated veining to 3-5%. Veining is predominantly 10-30 mm [Vn1a] veins with lesser [Vn1c] veins that are up to 200 mm, and rare brecciated [Vn1b] veins. Occasional 20-50 mm grey, calcite-rich [Vn3] veins. Rare base metal sulfide [Vn2] veins. Weak base metal sulfide mineralization in select [Vn1] generation veins. Veins range from planar to weakly deformed with cuspate-lobate margins.

Widely to very widely spaced discontinuities, typically slightly rough to very rough joint surfaces with slightly to unweathered walls, very strong to extremely strong, fresh to sometimes slightly weathered.

Discontinuity apertures generally < 1 mm with occasional 1-5 mm, some crushed rock (clayey or sandy) infill, some calcite coatings, primary joint orientations approximately 20-30° and 60-70° to core axis.

From 48.28 m to 50.12 m: Light grey, strongly silicified silica cap [H8] interval. Most of original texture overprinted.

At 57.87 m: Weakly-healed (breccia) planar fault, 30-40 mm length.

From 57.91 m to 95.68 m: Very widely to extremely widely spaced discontinuities.

Below 182.00 m: Relatively weak veining with 0-1.5% veining overall. Locally slightly stronger short [Vn1a] networks and larger [Vn1] veins. Veining consists predominantly of [Vn1a] veins with lesser [Vn3] and rare [Vn1b] and [Vn1c] veins. Veins are planar to weakly deformed and occasionally have cuspate-lobate margins.

From 187.43 m to 203.36 m: Decreased discontinuity spacing (moderate to widely spaced), joint apertures 1-2 mm, several minor 3-15 mm aperture faults with gougey or brecciated infills.

Packer Test 6: 187.74 m to 190.80 m, K ≤ 10^{-8} m/s.

Packer Test 4: 196.58 m to 201.28 m, K ~ 5×10^{-8} m/s.

END OF HOLE at 255.28 m.

NOTES
1) Bottom of borehole backfilled with cement-bentonite grout and Van Ruth plug installed at 205.94 m.
2) Installed 60.3 mm outer diameter schedule 80 polyvinyl chloride standpipe piezometer with 0.020 in slot size screen from 204.45 m to 195.30 m.
3) Filter sand (10-20 mesh size) placed around screen zone from 204.83 m to 193.49 m.
4) Bentonite pellet seal (coated, 1/4") placed above screen zone from 193.49 m to 189.66 m.
5) Water level measured after piezometer installation on 4 July 2018 at 112.60 m bgs.

OVERBURDEN (0.00 m to 2.77 m)

INTENSELY-SILICIFIED CONGLOMERATE [H8] (2.77 m to 8.20 m)
Grey, strongly silicified interval. Ghosted textures suggest original rock type was [S3]. Approximately 5% quartz veins as disarticulated [Vn1a] veins. Strong silicification of host and most fragments, minor sericite alteration of clasts.

Close to moderately spaced discontinuities, slightly rough joint surfaces with slightly to highly weathered walls, very strong to extremely strong, slightly weathered.

Discontinuity apertures generally < 1 mm, commonly with iron oxide staining on joint surfaces, some sand infill, primary joint orientations approximately 30° and 60° to core axis.

At 3.75 m: Weakly developed fault zone with minor fault gouge, 20 mm length.

At 6.17 m: Moderately developed fault zone with minor fault gouge, 170 mm length.

CONGLOMERATE [S3] (8.20 m to 29.80 m)
Grey-green, matrix-supported conglomerate with sub-rounded to rounded coarse, granular to pebble sized clasts. Clasts range from 2-100 mm and are commonly strongly sericite altered. Quartz veining, mostly disarticulated [Vn1a] veins and disarticulated and deformed [Vn1c]/[Vn1b] vein networks. Moderate vein associated silicification, with sericite alteration of fragments/clasts and chlorite alteration that is patchy throughout host matrix.

Moderately spaced discontinuities, slightly rough joint surfaces with variable but mostly highly weathered walls, very strong to extremely strong, slightly weathered to fresh.

Discontinuity apertures generally 0.5-5 mm, some iron oxide staining on joint surfaces in shallower part of unit, some crushed/disintegrated rock (clayey or sandy) infill, minor calcite coatings, variable joint orientations.

From 11.40 m to 19.14 m: Four minor to moderately developed fault zones with some fault gouge, 15-140 mm length.

WEATHERING GRADE: FRESH, SLIGHTLY, MODERATELY, HIGHLY, COMPLETELY, SOIL
STRENGTH GRADE: EXT. WEAK, V. WEAK, WEAK, MED. STRONG, STRONG, V. STRONG, EXT. STRONG
RQD: V. POOR, POOR, FAIR, GOOD, EXT. GOOD
FRACTURE INTERCEPT: V. CLOSE, CLOSE, MODERATE, WIDE

INTENSELY-SILICIFIED CONGLOMERATE [H8] (29.80 m to 42.20 m)
Grey, strongly silicified interval. Ghosted textures in the top portion of the interval suggest original rock type was [S3]. Mostly [Vn1c]/[Vn1b] vein networks. Moderate brecciation of host in [Vn1b]. Minor pyrite mineralization along vein selvages. Strong silicification of host matrix and clasts, minor sericite alteration is localized to few clasts/phenocrysts.

Moderate to widely spaced discontinuities, slightly to very rough joint surfaces with slightly weathered to unweathered walls, extremely strong, fresh to slightly weathered.

Discontinuity apertures generally < 1 mm, some sandy or clayey infill, minor calcite coatings, variable joint orientations.

SANDSTONE/ARENITE [S4-Vsf] (42.20 m to 159.45 m)
Medium greenish-grey, massive, silty to coarse sand [S4-Vsf]. Rare < 1 m interbeds of [S3] as observed above. Occasional calcite-pyrite concretions. Weak to moderate chlorite alteration of host matrix, with stronger chlorite alteration of clasts. Weak pervasive silicification of host matrix, with stronger alteration related to veining (high-fluid pathways). Pyrite appears as large clotty replacement of clasts and weakly disseminated throughout.

Widely to very widely spaced discontinuities, slightly rough to very rough joint surfaces with mostly slightly weathered to unweathered walls, very strong to extremely strong, fresh.

Discontinuity apertures generally < 1 mm, occasional crushed rock (clayey) or sand/silt infill, primary joint orientations approximately 30° and 60° to core axis.

From 42.20 m to 61.10 m: Moderately spaced discontinuities, mostly slightly rough joint surfaces with slightly to moderately weathered walls, extremely strong, slightly weathered. Discontinuity apertures generally < 1 mm, occasional crushed rock infill, primary joint orientation approximately 30° to core axis.

From 53.53 m to 55.20 m: Zone of discontinuities with crushed rock infill, aperture range 1-80 mm.

FILL and OVERBURDEN (0.00 m to 3.10 m)

CONGLOMERATE [S3-Poly] (3.10 m to 160.00 m)
Grey-green polymictic conglomerate. Clasts are dominantly subrounded with some subangular, 60% mafic and 40% lighter coloured. Possible [S4] clasts. Weak, shallow-angled imbrication of clasts (5-10°). Trace concretions with dark grey centres surrounded by a pale green rim. Concretions range from 10-100 mm. Phyllic alteration. Minimal veining, localized 10-30 mm vein structures. Trace [Vn2] with galena, sphalerite, acanthite.

Widely to extremely widely spaced discontinuities, slightly to very rough joint surfaces with typically slightly weathered walls, very strong to extremely strong, fresh.

Discontinuity apertures generally < 1 mm, some crushed rock infill, some calcite coatings, primary joint orientation approximately 40° to core axis.

From 3.10 m to 49.34 m: Close to widely spaced discontinuities, slightly rough joints with variably weathered variably slightly to highly weathered walls, very strong, slightly weathered to fresh. Discontinuity apertures generally < 1 mm with some 1-5 mm at shallower depths, common iron oxide staining on joint surfaces, some clay infill, some calcite coatings, highly variable joint orientations.

At 15.60 m: Fault zone 1.5 m long, sub-parallel to core axis, some fault gouge.

CONGLOMERATE [S3-Poly] (195.00 m to 241.00 m)
Grey-green polymictic conglomerate. Clasts are dominantly subrounded with some subangular, 60% mafic and 40% lighter coloured. Possible [S4] clasts. Weak, shallow-angled imbrication of clasts (5-10°). Trace concretions with dark grey centres surrounded by a pale green rim. Concretions range from 10-100 mm. Occasionally interbedded with [S4-Vsf] beds up to 1 m. Minimal veining, localized 10-30 mm vein structures. Trace [Vn2] with galena, sphalerite, acanthite.

Extremely strong, fresh.

FILL and OVERBURDEN (0.00 m to 3.80 m)

CONGLOMERATE [S3-Poly] (3.80 m to 91.92 m)
Grey-green polymictic conglomerate. Clasts are dominantly subrounded with some subangular, 60% mafic and 40% lighter coloured. Possible [S4] clasts. Weak, shallow-angled imbrication of the clasts (5-10°). Trace concretions with dark grey centres surrounded by a pale green rim. Concretions range from 10-100 mm. Phyllic alteration. Overall hole has weak veining with 0-1% veining consisting of 10-30 mm [Vn1a] and [Vn3] veinlets/veins. Veins are weakly deformed and occasionally have cuspate-lobate margins.

Widely to very widely spaced discontinuities, slightly rough to very rough joint surfaces with moderately weathered to unweathered walls, very strong to extremely strong, fresh.

Discontinuity apertures generally < 1 mm, some crushed rock infill, some calcite coatings, primary joint orientation approximately 60-70° to core axis.

From 3.80 m to 20.97 m: Closely to widely spaced discontinuities, slightly rough joint surfaces with slightly to highly weathered walls, very strong, slightly weathered.

From 3.80 m to 48.54 m: Iron oxide staining on joint surfaces.

At approximately 17 m: Minor loss of drilling fluid circulation.

OVERBURDEN (0.00 m to 2.96 m)

SANDSTONE/ARENITE [S4-Vsf] (2.96 m to 35.20 m)
Light grey, fine-grained sandstone. Silicification is pervasive as well as areas of patchy sericite and oxide alteration along fracture surfaces. Large fault zone areas containing gouge. Primarily [Vn0] and [Vn3] veining ~2-5%. [Vn0] veins have coarse grained pyrite mineralization. Pyrite also disseminated coarsely throughout the matrix. Trace ankerite within [Vn3] veins.

Widely spaced discontinuities, variable joint condition, extremely strong, fresh to slightly weathered.

Discontinuity apertures generally < 1 mm, some sand/silt infill, variable joint orientations.

From 2.96 m to 11.97 m: Moderately spaced discontinuities, strong to very strong, slightly weathered, some iron oxide staining on joint surfaces.

At 13.33 m: Fault, 10 mm aperture, gouge infill, sub-parallel to core axis.

Project No.: 1008-022
Location: CWP Pad B

Co-ordinates (m): 427,011E - 6,258,840N
Ground Elevation (m): 1,372.6
Survey Method: Surveyed co-ordinates
Datum: UTM NAD 83 Zone 9
Plunge (°): -90
Trend (°): 000

Drill Designation: Heliportable
Drilling Contractor: HY TECH
Drill Method: DIAMOND CORING
Core: PQ
Fluid: Polymer
Cased To (m) : 2.0

Start Date: 10 JUL 16
Finish Date: 11 JUL 16
Final Depth (m): 22.4
Depth To Top Of Rock (m): 1.9
Logged By: JRW, SH
Reviewed By: TWC

Depth (m)	INSTRUMENTATION & HOLE COMPLETION DETAILS	DRILLING ACTION OR SAMPLE TYPE	GEOTECHNICAL DESCRIPTION, MAJOR DISCONTINUITIES, AND ADDITIONAL NOTES

Appendix E: Simulated Drawdown (2019-2029)

NEWCREST

PRETIUM RESOURCES INC.

A member of the Newcrest Group of companies

Figure E-1: Simulated average annual drawdown in wells upgradient of the VOK (2019-2029). Underlined well ID indicates location was calibrated in baseline model.

Figure E-2: Simulated average annual drawdown in wells south of the VOK (2019-2029).

Figure E-3: Simulated average annual drawdown in wells west of West Zone (2019-2032). Underlined well ID indicates location was calibrated in baseline model.

Figure E-4: Simulated average annual drawdown in wells east of West Zone (2019-2029). Underlined well ID indicates location was calibrated in baseline model.

LORAX ENVIRONMENTAL

Authorship

This report was prepared by Lorax Environmental Services Ltd. (Lorax) for Pretium Resources Inc. (Pretium), a member of the Newcrest Group of companies. The report was written by Colin Fraser, M.Sc., P.Geo. with support from Joseph Xu, Ph.D., and reviewed by Scott Jackson, M.Sc., P.Geo. and Alison Shaw, Ph.D., P.Geo. Lorax Environmental Services Ltd. has relied on information available in the scientific literature and information supplied by Pretium in preparing this report.

TABLE OF CONTENTS II

LIST OF ACRONYMS AND ABBREVIATIONS VIII

1. INTRODUCTION
   1.1 PROJECT OVERVIEW 1-1
   1.2 PREVIOUS WATER BALANCE MODEL STUDIES 1-2
   1.3 STUDY OBJECTIVES AND REPORT STRUCTURE 1-5

2. DATA SOURCES
   2.1 ANNUAL MONITORING REPORTS AND RELATED STUDIES 2-1
   2.2 MINE PLAN DATA AND PROJECT SCHEDULE 2-3
      2.2.1 MINE PLAN DATA 2-3
      2.2.2 MINE PHASES 2-6
         2.2.2.1 CONSTRUCTION AND OPERATIONS 2-6
         2.2.2.2 CLOSURE AND POST-CLOSURE WATER MANAGEMENT ACTIVITIES 2-6
   2.3 CLIMATE DATA 2-6
      2.3.1 METEOROLOGICAL DATA FROM PRETIUM CLIMATE STATIONS 2-6
      2.3.2 CLIMATEBC 2-10
      2.3.3 GRIDDED CLIMATE DATASETS 2-11
      2.3.4 CLIMATE CHANGE SCENARIO DATA 2-12
   2.4 STREAMFLOW DATA 2-13
   2.5 GROUNDWATER RECHARGE TO THE UNDERGROUND MINE 2-20
   2.6 OTHER WATER MONITORING DATA 2-21
   2.7 BATHYMETRY SURVEYS 2-22

3. BRUCEJACK MINE WATER BALANCE MODEL
   3.1 OVERVIEW OF WBM 3-1
      3.1.1 KEY MODEL FEATURES FOR OPERATIONS AND CLOSURE 3-1
   3.2 CLIMATE DATA 3-7
   3.3 WATERSHED SCALE RUNOFF MODELLING 3-11
      3.3.1 MODEL DESCRIPTION 3-11
      3.3.2 APPROACH TO MODEL CALIBRATION 3-13
      3.3.3 SUMMARY OF RELEVANT CATCHMENT AREAS AND GLACIER EXTENTS 3-13
      3.3.4 SUMMARY OF THREE RESERVOIR MODEL COEFFICIENTS 3-14
      3.3.5 SUMMARY OF MODEL PERFORMANCE FOR THE CALIBRATION PERIOD (2015-2021) 3-15
   3.4 UNDERGROUND MINE SUB-MODEL 3-18
      3.4.1 OVERVIEW 3-18
      3.4.2 MODEL INPUTS AND ASSUMPTIONS, UNDERGROUND MINE 3-20
         3.4.2.1 CLOSURE AND POST-CLOSURE 3-21
   3.5 SURFACE WATER MANAGEMENT SYSTEM 3-23
      3.5.1 NON-CONTACT WATER DIVERSIONS 3-23
      3.5.2 CONTACT WATER COLLECTION SYSTEM 3-23
      3.5.3 FLOW MEASUREMENTS FOR THE CWCS 3-25
      3.5.4 SUMMARY OF INPUTS AND ASSUMPTIONS FOR THE CONTACT WATER COLLECTION SYSTEM 3-26
      3.5.5 CONTACT WATER POND 3-27
      3.5.6 LEAKAGE LOSSES FROM THE CWP TO WRTSF 3-28
   3.6 CWP, WTP AND MILL WATER BALANCE 3-29
      3.6.1 OVERVIEW 3-29
      3.6.2 INPUTS AND ASSUMPTIONS FOR THE CWP-WTP-MILL SUB-MODEL 3-33
      3.6.3 CWP-WTP-MILL SUB-MODEL CALIBRATION 3-36

3.7 SEWAGE TREATMENT PLANT 3-39
3.8 BRUCEJACK WRTSF 3-40
3.8.1 PRECIPITATION AND EVAPORATION 3-41
3.8.2 PLACEMENT OF WASTE ROCK AND TAILINGS IN WRTSF 3-41

4. WATER BALANCE MODEL RESULTS
4.1 OVERVIEW 4-1
4.1.1 OPERATIONS (2022-2029) 4-1
4.1.2 CLOSURE FILLING SCENARIOS AND POST-CLOSURE 4-3
4.2 OPERATIONS (2022-2029) 4-6
4.2.1 UNDERGROUND MINE 4-6
4.2.2 CONTACT WATER COLLECTION 4-6
4.2.3 CONTACT WATER POND 4-8
4.2.4 CLARIFIER, WTP AND TREATED WATER TANK 4-10
4.2.5 RECLAIM DIVERSION FROM BJ 3.10 WEIR 4-11
4.2.6 FRESHWATER TANK 4-12
4.2.7 WATER DEMAND AND ORE PROCESSING 4-13
4.2.8 SEWAGE TREATMENT PLANT 4-18

1. Introduction

1.1 Project Overview

Pretium Resources Inc. (Pretium), a member of the Newcrest Group of companies (Newcrest), owns and operates Brucejack Mine, a gold-silver mine located in the Coast Mountains of northwest British Columbia. The mine site (all mine infrastructure west of the upper Knipple Glacier) is situated within the Brucejack Creek watershed, which is a small headwater sub-basin within the Sulphurets Creek watershed. Sulphurets Creek is a tributary of the Unuk River that flows southwest, eventually discharging to the Pacific Ocean northeast of Ketchikan, Alaska.

Peaks surrounding the mine site reach elevations of approximately 2,400 masl and icefields surround the property to the north, west, south, and east. The property lies in a transition zone between the very wet coastal and drier interior regions of BC. Local climate is dominated by weather systems generated from the Pacific Ocean, and orographic effects caused by the local mountain topography produce high spatial variability in snowfall, rainfall, air temperature and snowmelt. In addition, extensive glaciation within the Brucejack watershed produces high runoff volumes in summer months, when air temperatures reach their annual maxima. Accordingly, the humid climate and physical characteristics of the region result in dynamic streamflow conditions and high annual runoff rates in local catchments.

Infrastructure for the Project was constructed over an approximately 2-year period beginning in September 2015. Critical infrastructure was sited to take advantage of local topography and accommodate environmental considerations, while avoiding avalanche hazards. An as-built general arrangement for the mine site is presented in Figure 1-1 and shows the following:

- The location of mine site infrastructure, including the location of a non-potentially acid generating (NPAG) quarry at km 72 of the Brucejack Access Road, with reference to the Brucejack watershed and the waste rock and tailings storage facility (WRTSF).
- Roads and various pads/laydown areas which provide access to mine site power distribution systems, the Valley of Kings (VOK) and West Zone (WZ) portals, camp accommodation and food services complexes, various maintenance/storage buildings and a sewage treatment plant (STP).
- The mill building, which contains ore processing circuits, a water treatment plant (WTP), a paste backfill plant and a metallurgical laboratory.

- Water management infrastructure, including diversion channels for non-contact water, contact water interceptor ditches, a contact water drainage collection system, plus sumps and collection areas to direct runoff to a contact water pond (CWP) and the WTP, as required.
- A waste rock platform and subaqueous waste rock disposal area in the WRTSF, with turbidity curtains and other measures in place to minimize and contain resulting suspended sediments.
- A subaqueous tailings disposal area in the deepest part of the WRTSF, using thickened tailings discharged at depth to minimize the release of suspended sediments. Pipelines used to transport tailings and waste to the WRTSF are also shown in Figure 1-1.

1.2 Previous Water Balance Model Studies

BGC (BGC, 2015a) prepared a site-wide water balance model (WBM) to support preparation of the 2015 Brucejack Mine Application for *Mines Act* (MA) and *Environmental Management Act* (EMA) Permits (Pretium, 2015); this application considered ore throughput at an average of 2,700 tonnes per day (tpd). BGC also updated the WBM in 2017 to support permitting of the mine at 3,800 tpd for a period of approximately 14 years (BGC, 2017c). Over time, a generally consistent model architecture was used by BGC, noting that new data and information offered opportunities for WBM refinement. The BGC water balance model was encoded at a monthly time step in MS-Excel software, where future mine site water balance conditions were resolved for a base case which considered average monthly climate conditions.

By 2017, much of the technical details of the as-built Brucejack Mine general arrangement and water management system were encoded into the MS-Excel model, with methodology in place to estimate: water volumes produced within the underground mine; the collection and conveyance of contact water from mine footprint areas; the accounting of reclaim water usage; and use of Project infrastructure such as the WTP to meet water use requirements of the mill, with excess treated effluent released to the environment, when mill water requirements are fully met. The most recent version of the WBM (BGC, 2017c) also assessed different scenarios for waste rock placement and tailings deposition.

FIGURE: 1-1

P:\@Drafting\Brucejack\Drafting Figures\MXD\2022 WQ Infrastructure\Brucejack Mine General Arrangement_Water Balance_F1-1.mxd

In 2020, the site-wide water balance and water quality models were updated as required by Brucejack Mine *Environmental Management Act* Permit PE-107835 and *Mines Act* Permit M-243 (2020 Mine Plan and Reclamation Program Update; Pretium, 2020c) (2020 Update). Condition 5.6 (Mine Data and Water Quality Modelling Review) of PE-107835 stipulates the permittee must conduct a review of the environmental monitoring required under the permit and reassess predictive modelling with respect to the environmental impacts. Condition D.4(e) Water Quality Predictions, including the requirement to validate and refine predictions based on site-specific monitoring information and Condition E.14(b) which requires compilation and interpretation of monitoring data as part of the Mine Plan and Reclamation Program Update, are relevant permit conditions under M-243.

Beyond the impetus of the 2020 Update, several other factors motivated the update of the site-wide WBM. First, a considerable amount of site-specific climate and streamflow data has been collected at the mine site since the WBM was last updated. For example, several years of additional climate data have been collected at the Valley of Kings (VOK) climate station (elevation 1,503 masl) and streamflow data from gauges situated below the WRTSF at BJ 3.10 and BJ 1.74. Furthermore, new datasets including those offered by ClimateBC, the Pacific Climate Impacts Consortium (PCIC) and Scenario Network for Alaska and Arctic Planning (SNAP) were incorporated into the revised WBM for the mine.

In addition, more than 2.5 years of mine site water monitoring data (*i.e.*, data associated with diversions, collection basins, tanks, pipelines and ponds) had been collected at the mine site, between July 2017 January 2020. These high frequency (hourly, daily) monitoring data capture important details related to the capture, use, recycling and discharge of contact and freshwaters at the mine site. Finally, monthly WBM outputs in Excel format were traditionally read into the Brucejack Mine Water Quality Model (WQM) which is a management tool configured using GoldSim environmental modelling software (GoldSim Technology Group LLC; www.goldsim.com). By modernizing the WBM into a software platform common to the WQM, there are obvious efficiencies and benefits to be gained by the end-user. GoldSim was specifically designed to facilitate problem solving in the water resource sector, thus a highly suitable software package to complete any proposed WBM and WQM updates for the Brucejack mine site.

1.3 Study Objectives and Report Structure

The objectives of this study are to:

- Using the 2020 WBM as a basis (Lorax, 2020), developed a revised WBM that supports an updated water quality model (WQM) as required for the 4950 tpd Joint M-243/PE-107835 Amendments Application (4950 tpd Joint Application). Note the revised WQM is described in full under separate cover (Lorax, 2023b).
- Review and present the data used to support development of the revised site-wide WBM, including inputs from an updated mine plan, relevant monitoring studies, design/engineering studies, and operational water monitoring datasets. Key information is presented in Section 2 and Section 3 of this report.
- Describe the WBM architecture and outline all relevant inputs and assumptions within the model. Material presented in Section 3, including GoldSim wire diagrams and representative model outputs, address this study objective.
- Discuss the calibration approach and present calibration results for the WBM. This objective is also addressed in Section 3, where outputs are presented to demonstrate model performance at both the watershed-scale (*i.e.*, BJ 3.10, Brucejack Creek below the WRTSF), as well as at the spatial extent of the mine site (*i.e.*, WTP and mill complex).
- Present and synthesize the results from the GoldSim WBM model. Section 4 of the report is dedicated to the presentation of the study results. As part of this exercise, results are presented for operations (2022-2029) and closure/post-closure (2030-2050 time periods.
- Summarize study results, discuss model sensitivities, identify data gaps and outline recommendations for future modelling studies. Section 5 of the report presents this concluding information.

2. Data Sources

This section of the report presents the various data sources utilized in the WBM update, including inputs from an updated mine plan, relevant baseline studies (*i.e.,* climate, hydrology, hydrogeology), design/engineering studies, and operational water monitoring datasets.

2.1 Annual Monitoring Reports and Related Studies

This study is informed by the data collection and water modelling studies (water balance, groundwater and water quality) conducted for Brucejack Mine over the last nine years. Since 2013, annual monitoring reports for the meteorology, hydrology, hydrogeology, surface water quality and aquatic resources disciplines have been prepared by Brucejack staff and their technical consultants. Also, many technical studies have been completed at Brucejack Mine, several of which have advanced the understanding of mine site water balance conditions and the water management systems in place to safeguard the mine and receiving environment.

The following annual monitoring reports and datasets were reviewed to complete this study:

- Pretium Resources Inc. (Pretium) (2016). Brucejack Mine 2015 Annual Report for *Mines Act* Permit No. M-243 and *Environmental Management Act* Permits 107835 & 107025. Submitted to BC Ministry of Energy and Mines and BC Ministry of Environment. March 2016.
- Pretium Resources Inc. (Pretium) (2017). Brucejack Mine 2016 Annual Report for *Mines Act* Permit No. M-243 and *Environmental Management Act* Permits 107835 & 107025. Submitted to BC Ministry of Energy and Mines and BC Ministry of Environment. March 2017.
- Pretium Resources Inc. (Pretium) (2018a). Brucejack Mine 2017 Annual Report for *Mines Act* Permit No. M-243 and *Environmental Management Act* Permits 107835 & 107025. Submitted to BC Ministry of Energy and Mines and BC Ministry of Environment. March 2018.
- Pretium Resources Inc. (Pretium) (2019). Brucejack Mine 2018 Annual Report for *Mines Act* Permit No. M-243 and *Environmental Management Act* Permits 107835 & 107025. Submitted to BC Ministry of Energy and Mines and BC Ministry of Environment. March 2019.

- Pretium Resources Inc. (Pretium) (2020a). Brucejack Mine 2019 Annual Report for *Mines Act* Permit No. M-243 and *Environmental Management Act* Permits 107835 & 107025. Submitted to BC Ministry of Energy and Mines and BC Ministry of Environment. March 2020.
- Pretium Resources Inc. (Pretium) (2021). Brucejack Mine 2020 Annual Report for Mines Act Permit No. M-243 and Environmental Management Act Permits 107835 & 107025. Submitted to BC Ministry of Energy and Mines and BC Ministry of Environment. March 2021.
- Pretium Resources Inc. (Pretium) (2022). Brucejack Mine 2021 Annual Report for *Mines Act* Permit No. M-243 and *Environmental Management Act* Permits 107835 & 107025. Submitted to BC Ministry of Energy and Mines and BC Ministry of Environment. March 2022.
- Period of record daily and monthly streamflow datasets maintained by Newcrest Mining Limited for the BJ 3.10 and BJ 1.74 monitoring stations.
- Period of record daily and monthly climate datasets maintained by Newcrest Mining Limited for the Bowser, Scott Pass and VOK climate stations.
- Operational water monitoring datasets maintained by Newcrest Mining Limited and spanning the period March 2017 to April 2022.

Relevant to this technical study and WBM update, the following reports and guidance documents are notable:

- BGC Engineering Inc. (2013). Brucejack Project Feasibility Study, Water Management Plan. Final Report – Rev 1. Report prepared for Pretium Resources Inc.
- BGC Engineering Inc. (2015a). Brucejack Project – MA/EMA Permitting Phase – Brucejack Mine Water Balance Model, 2700 tpd Permit Application. Report prepared for Pretium Resources Inc.
- BGC Engineering Inc. (2015b). Brucejack Project – MA/EMA Permitting Phase – Numerical Hydrogeologic Model Update Report. Report prepared for Pretium Resources Inc.
- BGC Engineering Inc. (2017a). Contact Water Pond Hydrogeological Assessment. Project No.: 1008-022. Report prepared for Pretium Resources Inc. January 2017.
- BGC Engineering Inc. (2017b). Brucejack Mine, Assessment of Reclaim Water Volumes for 3800 tpd Permit Amendments. Doc. No. BJ-2017-56. Report prepared for Pretium Resources Inc. December 2017.

- BGC Engineering Inc. (2017c). Brucejack Mine Water Balance Model, 3800 tpd Permit Amendment Application. Document No.: BJ-2017-57. Report prepared for Pretium Resources Inc. December 2017.

- Lorax Environmental Service Limited (Lorax) (2020). Brucejack Mine: 2020 Water Balance Model Review and Update. Prepared by Lorax Environmental Services Ltd. for Pretium Resources Inc. Submitted July 2020.

2.2 Mine Plan Data and Project Schedule

2.2.1 Mine Plan Data

Mine plan data relevant to the WBM can be found within the 4950 tpd Joint Application (Pretium, 2023). Key tables for the WBM are re-produced in Appendix A, which include the following information:

- The Life of Mine (LOM) Ore Production Schedule.
- The Waste Rock Inventory, which includes accounting for total waste, waste to be used as fill in the underground mine and waste to be placed in the WRTSF.
- The Tailings Schedule, which includes separation of waste tonnages in terms of tailings to be placed in the WRTSF below water cover versus tailings placement in the underground mine as paste backfill.

To provide context for the reader, the processing of ore began at Brucejack Mine in July 2017 (Figure 2-2 and Figure 2-2 upper panel). Following start-up, ore processing ramped up to a rate of 2,700 tpd, remaining relatively constant until January 2019. Over the course of 2019, ore processing increased toward the allowable (as of December 14, 2018) permitted rate of 3,800 tpd. In the calendar years 2020, 2021 and 2022, mill feed was relatively constant and varied on average between 3,600-3,800 tpd.

As stipulated in the mine plan assessed for this application (*i.e.*, 4950 tpd, refer to Appendix A), mill feed from 2022 and 2023 is forecasted to be 3,800 tpd on a calendar year basis, which equates roughly to an ore processing rate of 1,390 kt/yr. Ore processing is forecasted

to increase slightly in 2024 prior to reaching maximum values for years 2025 through 2029 (approximately 1,800 kt/yr). Ore processing is scheduled to cease at the end of Q4 2029.

Figure 2-1: Mill feed rate (in dry metric tonnes) at the Brucejack mill for the period July 2017 through September 2022.

Total tailings produced under the 2022-2029 mine plan are shown in Figure 2-2, middle panel. Though proportions differ slightly by year, roughly 40% of produced tailings are scheduled to be placed as cemented backfill in the underground mine, whereas the remaining 60% is to be placed under permanent water cover in the WRTSF (Figure 2-2, middle panel). With respect to waste rock (total), tonnages produced are greatest on an annual basis through 2024, noting values are much lower for subsequent years (Figure 2-2, lower panel).

Figure 2-2: Life of Mine (LOM) Ore, Tailings Production and Waste Rock Tonnages for the Brucejack Mine. Shaded areas on each plot indicate measured values for the period 2017-22.

2.2.2 Mine Phases

2.2.2.1 Construction and Operations

Construction of major works related to ore processing and site-wide water management began in September 2015, with most activities completed by mid-2017. The processing of ore, including production and placement of tailings in either the WRTSF or underground mine, has been ongoing since July 2017.

Milling of ore is planned to continue through December 2029, as indicated in the 2022 LOM schedule (Appendix A).

2.2.2.2 Closure and Post-Closure Water Management Activities

Closure and post-closure activities relevant to the WBM are outlined in Chapter 3, Closure and Reclamation Update of the 2020 Update (Pretium, 2020c) and in the 4950 tpd Joint Application (Pretium, 2023). Briefly, the primary goals of closure and post-closure water management activities will be to minimize the long-term effects on the environment and return the site to as close to its pre-disturbance condition as possible without the need for long-term active water treatment. Therefore, several assumptions are encoded into the WBM with respect to these two Project phases. For example, closure is assumed to involve the removal of all structures and equipment, closure of the portals, flooding of underground mine workings, and site rehabilitation. At final closure, the WBM assumes two surface diversion channels will remain in place and the CWP will flood to the elevation of the current spillway, with overflow reporting to the WRTSF.

2.3 Climate Data

Four sources of climate data are used to setup and run water balance simulations: period of record data from the climate stations operated by Pretium; monthly synthetic climate data obtained from ClimateBC; daily gridded climate data available from the Pacific Climate Impacts Consortium (PCIC); and, monthly climate change scenario data made available by the Scenario Network for Alaska and Arctic Planning (SNAP).

ClimateBC - https://climatebc.ca/

PCIC - https://pacificclimate.org/data/daily-gridded-meteorological-datasets

SNAP - https://uaf-snap.org/climate-tools/download-raw-data/

2.3.1 Meteorological Data from Pretium Climate Stations

Each year, since 2013, Pretium has submitted an annual monitoring report which summarizes calendar year monitoring data and current state of understanding with respect

to climate conditions within the Brucejack Creek watershed (*e.g.*, Pretium, 2016; Pretium, 2017; Pretium, 2018a; Pretium, 2019; Pretium, 2020a; Pretium, 2021a). The locations of automated climate stations and snow courses maintained by Newcrest are shown in Figure 2-3.

Situated adjacent to the mine site, data from the VOK climate station (1,500 m asl) and snow course are most relevant to the set-up and execution of the Brucejack WBM. The VOK climate station is instrumented with research grade sensors and programmed to record the following parameters hourly: air temperature (min, max, mean), relative humidity, average wind speed and gusts, solar radiation, net radiation, atmospheric pressure and total precipitation. Measured data utilized in this assessment were compiled to daily and monthly timestep prior to use. The steps taken to post-process raw measured data to final values, such as the specifics relating to the correction of gauged precipitation data for wind and under-catch, are provided in the annual meteorology monitoring reports.

A sub-set of the measured climate record for the VOK climate station is shown in Figure 2-4. These data are essentially continuous and high-quality for the period of record September 2014 through October 2022. As such, they provide a sound representation of local climate conditions and reliable source of climate data to represent mine site water balance conditions over the past eight+ years.

2.3.2 ClimateBC

The ClimateBC data tool generates synthetic climate data for use in water resources applications and climate change studies in British Columbia. For a location of interest, outputs from ClimateBC include 56 seasonal and 168 monthly climate variables that are either directly calculated or derived. Methodologies related to ClimateBC are summarized in Wang *et al*. (2012) and at the host website: http://cfcg.forestry.ubc.ca/projects/climate-data/climatebcwna/.

To support the water balance update and other supporting studies associated with the 2020 5 Year Mine Plan Update (*e.g.*, set up and execution of groundwater modelling runs), air temperature, precipitation and potential evaporation data were extracted for grid points within the Brucejack watershed. Extracted data spanned 100 m elevation bands between 1,300 masl to >2,000 masl. Representative orographic gradients (*e.g.*, % change in precipitation per 100 m elevation gain) for the Brucejack Creek watershed were derived from the extracted data by re-arranging Equation 1 from the UBC Watershed Model Manual (Quick *et al.*, 1995):

$$P_2 = P_1(1+a)^{\Delta elev/100} \qquad (1)$$

where P_1 is precipitation at the lower elevation (mm), P_2 is precipitation at the higher elevation (mm), Δelev = difference in elevation between lower elevation and higher elevation, and α is the percentage change in precipitation per 100 m increase in elevation.

Recall from earlier discussion in Section 1 that the mine site is situated in a locale dominated by weather systems generated from the Pacific Ocean which are highly variable and also strongly influenced by orographic effects caused by the local mountain topography and the presence of glaciers. Similar to findings reported in BGC (2017c), raw precipitation outputs from ClimateBC were found to overestimate local precipitation conditions within the Brucejack watershed. However, the raw outputs from ClimateBC were readily adjusted to reflect 'true' conditions at the mine site, using five years of reference data at VOK climate station as a guide. For illustrative purposes, a comparison of adjusted annual precipitation from ClimateBC (*i.e.*, for grid point 56.453N, -130.189W and elevation 1,503 masl; approximate location of VOK climate station) and measured data from VOK climate station are shown below (Figure 2-5).

Overall, data from ClimateBC provide useful context with respect to long-term average precipitation for the mine site, the expected range and variability in precipitation from year-to-year, as well as the magnitude of annual precipitation measured at the mine site since 2014. For example, mean annual precipitation at the elevation of the VOK climate station is inferred to be on the order of 1,950 mm and annual depths are expected to vary on an annual basis between 1,400-2500 mm.

Figure 2-5: Time series comparing ClimateBC and measured precipitation outputs for VOK climate station.

2.3.3 Gridded Climate Datasets

For years prior to 2022, climate data from the VOK climate station are read directly into the WBM. To run the model forward, daily air temperature and precipitation data are required. This requirement could be met by looping, or averaging, the relatively short-measured record for the VOK station, to represent future conditions. However, gridded climate datasets are readily available for Western North America at a daily time step and well-suited for use in WBM studies such as this one.

Following a review of available datasets, data from the PNWNAmet dataset were downloaded from the Pacific Climate Impacts Consortium (PCIC) data portal, for nearest grid points to the mine site (https://www.pacificclimate.org/data/daily-gridded-meteorological-datasets). These gridded data have daily frequency, span the period 1945-2012 period, and are described by Werner *et al*. (2019). Furthermore, downloaded data cover the following parameters: minimum temperature, maximum temperature, average temperature and precipitation. Note that additional specifics describing the use of climate data in the WBM are presented in Section 3.2.

Like data from ClimateBC, gridded precipitation from PNWNAmet were found to overestimate mine site conditions. However, since the base data underpinning both ClimateBC and PNWNAmet are the same, these precipitation data were adjusted prior to use (*i.e.,* based on VOK measured data) following scaling procedures outlined in Lorax (2020).

2.3.4 Climate Change Scenario Data

In the future, conditions at the Brucejack Creek watershed are expected to be warmer and slightly wetter than today. Accordingly, there are merits in exploring WBM sensitivity to these potential changes, with emphasis on years corresponding to proposed operations (2022-2029) and closure (2030-2033) activities.

Climate Change Scenario Data used in this assessment were obtained from the Scenario Network for Alaska and Arctic Planning (SNAP, University of Alaska – Fairbanks). Specifically, Projected Monthly and Derived Air Temperature/Precipitation Products - 2km CMIP5/AR5 files were downloaded, which are gridded climate datasets spanning the period 2006-2100 (SNAP, 2020). SNAP serves out data for three Representative Concentration Pathway (RCP) scenarios (*i.e.*, RCP4.5, RCP6.0 and RCP8.5), five separate climate models, as well as a 5-model composite average for each RCP scenario. Monthly climate change scenario data for the 5-model average RCP6.0 scenario were used to inform the WBM update, although other datasets and scenarios can be incorporated into the WBM in the future.

Figure 2-6 shows future predicted changes for air temperature and precipitation for the mine site separated into four 20-year bands. By the end of the century (*i.e.*, 2100) annual air temperature is projected to increase by 3°C over current conditions. An increase in precipitation is also projected for the Brucejack Creek watershed, though changes over time are relatively minor and amount to a 9% increase in total precipitation by 2100, for the 5-model average under the RCP6.0 scenario. In contrast, predicted changes for the operations and closure phases (*i.e.*, 2022-2033) are minor, showing increases in annual temperature and precipitation of 0.5°C and 3%, respectively (Figure 2-6).

Figure 2-6: Summary of RCP6.0 climate change scenario trends for the Brucejack Mine. Data shown are 5-model average results and show predicted air temperature and precipitation increases for four future time periods (SNAP, 2020).

2.4 Streamflow Data

The Brucejack Creek catchment (drainage area 8.5 km^2 at station BJ 1.74) is a small headwater sub-basin within the larger Sulphurets Creek watershed (drainage area 300 km^2 at the confluence with the Unuk River). The catchment is in a glaciated, alpine environment, with its uppermost portion flowing into the WRTSF (drainage area 6.7 km^2 at BJ 3.10). About 17 km downstream of Sulphurets Lake, Sulphurets Creek meets with the larger Unuk River which ultimately flows into the Pacific Ocean, northeast of Ketchikan, Alaska (Figure 2-7).

Brucejack Mine's Hydrometric Monitoring Program aims to collect and analyze hydrometric data in compliance with monitoring provisions of Effluent Permit PE-107835 issued under the provincial Environmental Management Act and the Metal and Diamond Mining Effluent Regulations (MDMER) of the federal Fisheries Act. The active hydrometric monitoring program consists of three streamflow monitoring stations and a level monitoring station (Figure 2-8; Table 2-1): hydrometric gauges at BJ 3.10 and BJ 1.74, located along Brucejack Creek; a hydrometric gauge at SC-1 located along Sulphurets Creek; and the BJ WRTSF level monitoring station. Record periods for the three hydrometric stations are as follows: BJ 1.74 (2008 – present), BJ 3.10 (2014 – present), and SC-1 (2016 – present). The most-downstream node considered in the site-wide WBM coincides with the location of the BJ 1.74 monitoring station.

Watershed	Area (km^2)
Bell-Irving River	5338
Brucejack Creek	9
Unuk River (at international border)	1504

[a] *UTM Zone 9U, NAD 83*
[b] *Originally BJL-H1, relocated to BJ 1.74 in 2014.*
[c] *Discharge measurements conducted on the channel downstream from the weir. No visible tributaries are located between the station and gauging section.*

Hydrometric monitoring standards adopted by Pretium are based on standards published by the British Columbia Ministry of Environment (MECCS, 2018), the United States Geological Survey (Turnipseed and Sauer, 2010), and the International Organization for Standardization (ISO, 2007). Standard discharge measurement techniques (MECCS, 2018) are employed at stations BJ 3.10, BJ 1.74, and SC-1 (*e.g.*, 20-panel waded measurements with a current meter) whereas methods used in the development of stage-discharge rating curves follow as close as possible guidelines by MECCS (2018) and ISO (2010). A stage-discharge rating curve is an empirical relation used to calculate streamflow (discharge) from continuously recorded water level data.

Rating curves for Brucejack monitoring stations are constructed using the Rating Development Toolbox within Aquarius Time-Series (AQTS). In concept, discharges and water levels are manually measured over a range of flow conditions (*i.e.*, low to high) to generate the curve. Typically, a minimum of ten discharge measurements across a range of stage and streamflow conditions are recommended to develop a robust stage discharge relationship (MECCS, 2018), a threshold that is well exceeded for the Brucejack hydrometric stations. Rating curves for monitoring stations are updated annually as new data becomes available and/or stream channel conditions change.

Each year since 2013, Pretium has prepared an annual monitoring report which summarizes calendar year monitoring data and current state of understanding with respect to streamflow conditions within the Brucejack Creek watershed (*e.g.*, Pretium, 2016; Pretium, 2017; Pretium, 2018a; Pretium, 2019; Pretium, 2020; Pretium, 2021 and Pretium, 2022). The flow regimes of BJ 1.74 and BJ 3.10 is highly similar where daily/monthly patterns of streamflow at BJ 3.10 are strongly influenced by snow accumulation and snowmelt processes, where roughly 85% of runoff on an annual basis is expected to report to receiving streams between May and the end of October (Figure 2-9 and Table 2-2). By comparison, discharges and runoff depths for other months of the year (*i.e.*, November through April) are much lower. Winter streamflow rates are well characterized within the Brucejack Creek watershed and range typically between 0.05-0.120 m^3/s between December and April, at BJ 3.10. The transition from annual low flow conditions coincides with warmer air temperatures in the spring and the melting of snowpack. Measured discharges through open-water (ice free) months typically range between 0.5-2.5 m^3/s (Figure 2-9 upper panel, at BJ 3.10).

Figure 2-9: Streamflow measurements below the WRTSF outlet (BJ 3.10) for the period 2014-2021. Data for the station is presented in time series (upper panel) and flow duration curve format (lower panel).

2.5 Groundwater Recharge to the Underground Mine

Numerical groundwater modeling studies of the Brucejack mine were undertaken in 2013, 2014, and 2015 to support applications for an Environmental Assessment Certificate and *Mines Act* / *Environmental Management Act* permits. These modeling studies drew upon site investigations characterizing hydrogeological conditions initiated in 2010, based on drilling, hydraulic testing, and monitoring well and vibrating wire piezometer installations. Data available through late 2014 were used in conceptual and numerical groundwater model development, calibration, and benchmarking. It is important to note that the numerical groundwater model was updated in support of the 2020 Mine Plan and Reclamation Program Update. Briefly, the 2020 groundwater model update and work completed since that time builds upon the assumptions underpinning the 2015 groundwater model, incorporating a longer water level and underground dewatering records, and is constructed using FEFLOW 7.2 simulation software (DHI, 2020).

In addition to modelling, routine groundwater quantity and quality monitoring has been ongoing at the Brucejack Mine site since 2011. Hydrogeological field programs comprised of drilling, hydraulic testing, and monitoring well installation were undertaken in 2016 and 2018 (BGC, 2017; BGC, 2019). The 2018 field investigation established 14 new monitoring wells, fulfilling *Environmental Management Act* Permit PE-107835 and *Mines Act* Permit M-243 requirements.

In summary, the groundwater flow system at the Brucejack Mine has been conceptualized to provide estimates of groundwater inflow to the existing and future underground mine workings during operations and closure, and for groundwater seepage flow paths during post-closure (Lorax, 2023a). An example of the measured and modelled GW inflow data records used in the WBM is shown in Figure 2-10 noting GW inflow to the underground mine shows strong seasonality, where fluxes are much higher in the spring, summer, and autumn, than during the winter. Measured data for the pre-2019 period show GW inflow varies between 30-80 m^3/hr on an annual basis. By comparison, modelled rates of GW inflow are predicted to become progressively higher and range from 60-160 m^3/hr on an annual basis, by the end of mining, when the underground mine is at full extent.

Figure 2-10: Measured (blue) and modelled (red) time series of GW inflow (or recharge) to the underground mines.

2.6 Other Water Monitoring Data

In addition to climate and streamflow monitoring activities, Pretium maintains a water monitoring database (*i.e.,* 12-hour and daily time-step) related to water infrastructure and water management at the mine site. Available data span the period from commencement of ore processing (July 2017) with data collection ongoing.

Set-up and re-configuration of the WBM benefited from water monitoring data that provide representative information on:

- The magnitude of runoff volumes associated with the contact water collection system.
- Pumping strategies (*i.e.*, flow rates, seasonal timing) between the CWP and the WTP, and steps taken to manage CWP stage/volume, over the course of the year.
- Freshwater use within the underground mine for drilling and dust suppression purposes. The underground mine is serviced by flows from the freshwater tank (FWT).
- The magnitude and seasonal patterns of reclaim water diversions associated with Pretium's permitted water allocation from Brucejack Creek below the WRTSF.

- The fate of treated effluent from the WTP, including amounts used in the mill to support ore processing, volumes recycled back to the CWP, and/or released to the Brucejack WRTSF via the treated water tank (TWT) when water supply requirements are fully met.
- The water volumes associated with the production of concentrate, paste backfill and tailings slurry.

Figure 2-11 and Figure 2-12 show representative examples of the available monitoring data for key water infrastructure and water management pathways (2017-2022) and are discussed further in Section 3 and Section 4 of this report.

2.7 Bathymetry Surveys

Pretium completed bathymetric surveys of the WRTSF in 2015 and each year thereafter since 2018. A comparison of the completed surveys confirms shallowing and volume loss over time in the WRTSF on account of waste rock and tailing placement (Figure 2-13).

For example, WRTSF volume was estimated to be 30.3 Mm^3 in 2015 versus 24.7 Mm^3 in 2022, and data from these two dates indicate the reduction in maximum depth of the facility was approximately 25 m between sampling dates. By 2029 and following placement of all waste rock and tailings outlined in the LOM schedule, the final volume in the WRTSF will be on the order of 21 Mm^3.

3. Brucejack Mine Water Balance Model

3.1 Overview of WBM

Overview schematics of the Brucejack Mine WBM are shown in Figure 3-1, Figure 3-2 and Figure 3-3. Figure 3-1 and Figure 3-2 show conceptual layouts of the mine site with reference to the Brucejack watershed and WBM nodes established on Brucejack Creek below the mine site for operations and post-closure respectively. Arrows in Figure 3-1 and Figure 3-2 connect the identified components of the WBM and represent surface conveyances, flowpaths, pipelines and material flows, noting that different line colours are used to distinguish 'flow' associated with non-contact/background, water treatment plant effluent, surface contact and mine contact waters.

Figure 3-3 is a screen capture from the GoldSim model and shows the main containers of the model (boxes) and any inter-connections between containers, depicted by arrows. Within each container shown in the plot, more detailed sub-models and time series inputs are encoded. The sections of text below describe main elements of the WBM, assumptions within each, and introduce the sub-models that are the working parts of the overall WBM. For reference, Figure 3-4 is provided and gives an introduction to the Input, Function and Stock elements that appear in many GoldSim wire diagrams presented later in this section of the report (*e.g.*, Figure 3-10 and Figure 3-17).

3.1.1 Key Model Features for Operations and Closure

The bullets below outline the main water management components represented in the WBM for the operations phase (Figure 3-1):

- The WBM considers a contact water pond (CWP) which is assumed to receive approximately 60% of surface runoff from the mine site contact water collection system (primarily the mill and lower camp pads). Captured contact water is pumped to the WTP for treatment. The remaining 40% is assumed to be collection system leakage that reports directly to the waste rock tailings storage facility (WRTSF) or Brucejack Creek below the WRTSF;
- Sump waters from the underground mine, which includes groundwater inflows, paste backfill bleed water (*i.e.*, the excess water not consumed in the paste backfill cementation reaction) and water from the FWT that is directed to the underground mine to support drilling/dust suppression activities;

  - Like water reporting to the contact water collection system (CWCS), water volumes captured in the mine sumps are pumped to surface and report to the clarifier;

- The WBM accounts for make-up/reclaim water taken from BJ 3.10 and necessary to meet mill demand. Reclaim from BJ 3.10 is directed to the FWT to supplement water requirements below ground and in the mill;
- A water treatment plant (WTP), which treats water from the CWP and the underground mine (via the clarifier). Treated effluent from the WTP is used in the mill process, with any excess not required for process discharged to the WRTSF, or re-cycled back to the CWP;
- Discharge of effluent from a sewage treatment plant (STP) to the WRTSF;
- A mill which discharges a tailings slurry to the WRTSF and/or conveys paste backfill to the underground mine;
- The conveyance of contact flows from the km 72 NPAG quarry and the WR platform to the WRTSF via surface runoff; and
- Deposition of waste rock sub-aqueously in the WRTSF and to the underground mine as backfill.

At closure, the WBM assumes as base case that mine facilities will be decommissioned, and the underground mine workings will be flooded over a seven-month period, starting in January 2030 (Lorax, 2023a). The natural flooding from groundwater inflows will be accelerated by pumping water from the WRTSF into the underground mine at a rate equal to 70 m^3/hr (~ 50,000 m^3/month) between January and April and then at an increased rate equivalent to 20% of the mean monthly flows at BJ 3.10 during May June and July. In closure, underground mine water will be treated by the WTP at a rate of 10,000 m^3/day and recirculated back underground throughout the flooding period, as well as for an additional eight months to ensure that water quality is effectively managed.

The WBM also considers the post-closure phase. The following mine-related components are relevant for this Project phase: flows from the km 72 NPAG quarry; flows from the reclaimed plant site; and drainages from the underground mine which flow to the WRTSF and Brucejack Creek via groundwater pathways. An overview schematic for the post-closure phase is shown in Figure 3-2.

Figure 3-2: Overview Schematic – Conceptual Layout for Post-closure

Figure 3-3: WBM Overview Schematic – Brucejack Mine, GoldSim Layout

Figure 3-4: Overview of Input, Function and Stock elements in GoldSim simulation software.

3.2 Climate Data

Climate data are used to drive several of the sub-models within the WBM. This is evident in Figure 3-3 by the several 'arrow' connections between the Climate folder and other components of the WBM. Technical detail represented within the Climate container of the model is shown in Figure 3-5. At the right side of schematic (Figure 3-5), period of record data recorded by the VOK climate station are organized into air temperature and precipitation read-in tables (grey shading). On the left side of the Figure 3-5 (white and pink shading), long-term average synthetic climate data from PNWNAmet are similarly organized into air temperature and precipitation read-in tables. Finally, monthly climate change scenario data tables available from the Scenario Network for Alaska and Arctic Planning (SNAP) for RCP6.0, are shown in the centre of Figure 3-5 (blue shading).

Consistent with the 2020 5-Year Plan water balance model, Base Case results presented in Section 4 use climate data inputs in the current version of the WBM (based on the 4950 tpd Joint Application mine plan) as follows: VOK climate station measurements are read into the model for the pre-2022 time period at daily timestep; and for the period 2022-2100, average daily climate readings developed from a 30-yr portion of the PNWNAmet daily- gridded dataset, are continuously looped for the duration of the simulation (Figure 3-6, upper panel). Note that PNWNAmet data spanning the period 1983-2012 (see Section 3.3.3) are used to generate the long-term daily averaged air temperature and precipitation inputs which are continuously looped in the water balance model.

The GoldSim model is also constructed to read in daily variable climate inputs for the period 2022-2100 (Figure 3-6, middle panel) and daily variable climate inputs adjusted for future climate change for the period 2022-2100 (Figure 3-6, lower panel). Briefly, daily-varying climate readings developed from a 30-yr portion of the PNWNAmet daily- gridded dataset, are continuously looped, for the duration of these two climate input options (*i.e.*, variable climate case and variable climate case plus climate change). Upon instruction, GoldSim then 'time-steps' the variable climate inputs to produce 30 unique realizations of results, in essence, allowing a full range of meteoric conditions to be modelled upon each year of the Project timeline. Regarding air temperature and precipitation adjustments for future climate change, annual scalars are read into the WBM based on the RCP6.0 scenario developed from datasets prepared by the Scenario Network for Alaskan and Arctic Planning (SNAP) (refer to Section 3.3.4).

Figure 3-5: Schematic showing the Climate container of the Brucejack Mine WBM.

Figure 3-6 (a): Time series plots illustrating options for the input of air temperature (shown) and precipitation data (see Figure 3-6b) into the WBM. For the period 2022-2100, options include: looping of average daily climate data for the period (upper panel); looping of variable climate data for the period (middle panel); and looping of variable climate data adjusted for future climate change (lower panel).

Note: For each climate data input option, measured air temperature and precipitation data for the pre-2022 period are read into the model (blue shading). For the variable climate case and variable climate plus climate change case, only results for realization #1 (of n = 30) are shown in the plots above. Since the variable climate record used in the WBM is 30-years in length, the model can read in thirty realizations of climate input data and produce thirty unique realizations of WBM output for each year of any model simulation.

Figure 3-6 (b): Time series plots illustrating options for the input of precipitation data into the WBM. For the period 2022-2100, options include: looping of average daily climate data for the period (upper panel); looping of variable climate data for the period (middle panel); and looping of variable climate data adjusted for future climate change (lower panel).

Note: For each climate data input option, measured air temperature and precipitation data for the pre-2022 period are read into the model (blue shading). For the variable climate case and variable climate plus climate change case, only results for realization #1 (of n = 30) are shown in the plots above. Since the variable climate record used in the WBM is 30-years in length, the model can read in thirty realizations of climate input data and produce thirty unique realizations of WBM output for each year of any model simulation.

3.3 Watershed Scale Runoff Modelling

3.3.1 Model Description

A modified version of the Birkenes watershed model is used to replicate the streamflow regime within the Brucejack Creek watershed. This model is depicted in concept diagram and GoldSim coded format in Figure 3-7. The Birkenes model was developed as part of a research program to understand linkages between stream chemistry and flow in a small (< 1 km^2) catchment in southern Norway (*e.g.*, Christophersen and Seip, 1982; Seip *et al.*, 1985). Previous efforts on the WBM considered a similar approach, so the modelling concept (*i.e.*, simplified, reservoir-based watershed modelling) is not new (BGC, 2017c). However, any runoff modelling completed previously was undertaken at a monthly time step, whereas watershed model calibration and integration into the WBM is now handled at daily time step.

The Birkenes model represents the watershed using a series of connected reservoirs which aim to replicate a measured hydrograph by separating total discharge into three component flows: quick flow, or event runoff, which may be associated with melting of snowpack or summer storms; interflow, which is flow through shallow overburden material and soils; and baseflow, which in concept is the portion of the hydrograph which is derived from groundwater discharge. Conceptually, incoming precipitation is partitioned in the model to rain, or a snow reservoir, based on air temperature thresholds.

Rainfall is directed into Fast and Slow Surface reservoirs, which represent areas of fast runoff response, and slower-draining soil areas, respectively. Fast and slow surface recession flow from the surface storage reservoirs can go directly to surface discharge, or to the Deep Surface Water reservoir, depending on the fraction of remaining available storage in the latter. When the Deep Surface Water reservoir contains water, slow recession flow from the reservoir reports as baseflow. Withdrawals from these reservoirs are governed by constant proportional losses applied to the reservoir volume at a given time-step. As the reservoir volume is drawn down (assuming no additional inputs), the rate of withdrawal is reduced, and thus the outflow signature approximates a negative exponential decay function (*i.e.*, the recession curve).

Snow within the Snowfall reservoir remains in storage until snowmelt begins, which is controlled in the model using daily temperature-dependent melt functions. When snow within the Snow Reservoir melts, these waters can either report to other model reservoirs if they are depleted or generate quick flow following the mechanisms described for Rainfall. Over the course of a simulation, evaporation is withdrawn from both surface reservoirs (Fast and Slow), and from the Deep Surface reservoir, but at a lower rate. Similar to the handling for snow versus rain, evaporation is computed in the model using temperature-based controls.

Figure 3-7: Overview schematic of the Birkenes 3-reservoir model (left) and coding of the model in GoldSim (right panel)

3.3.2 Approach to Model Calibration

The watershed model was calibrated for the mine site using measured climate data for the VOK climate station and measured streamflow data for BJ 3.10, spanning the period January 2015 to December 2021. Therefore, the calibration effort was based on a seven-year measured climate and streamflow record. The overall approach to the calibration was to first develop and test a preliminary calibration for the Brucejack watershed (*i.e.*, 6.5 km^2), then build-out the various sub-models that appear in the WBM, by applying a generic set of watershed model parameters developed during the initial calibration process, to these sub-models. With reference to Figure 3-1 and Figure 3-2, runoff/discharge is derived for the following portions of the WBM, using a generic set of watershed model parameters: background runoff that reports to the WRTSF, background runoff that reports below BJ 3.10 but above BJ 2.62, background runoff that reports below BJ 2.62 but above BJ 1.74, as well as runoff from the footprints of the km 72 NPAG quarry and waste rock platform beside the WRTSF.

With all the modelling work completed in GoldSim, measured and modelled results at BJ 3.10 for the full seven-year timeframe were then carefully assessed. To evaluate the efficacy of the calibration and overall model performance, visual comparisons of time series results, statistical analyses using measures like the Nash-Sutcliffe Efficiency coefficient, and flow-duration curve comparisons, between measured and modelled data, were performed.

3.3.3 Summary of Relevant Catchment Areas and Glacier Extents

The sub-watershed models embedded into the GoldSim WBM generate runoff (depth in mm) which is subsequently converted to a flow rate, in m^3/s, based on catchment area. A summary of catchment areas relevant to the WBM setup is provided in Table 3-1.

When air temperatures are at their maximum and snowpack is fully melted, the WBM accounts for glacial melt using a temperature-dependent melt approach following the approach adopted by BGC previously (BGC, 2017c). A summary of glacier extents relevant to the WBM setup is also provided in Table 3-1.

Table 3-1:
Summary of catchment areas and footprints used in the WBM

Catchment	Total area (km^2)	Glacial footprint (km^2)
Background runoff to Brucejack WRTSF	5.41	0.43
Background runoff below BJ 3.10 and above BJ 2.62	0.78	0.27
Background runoff below BJ_2.62 and above BJ_1.74	1.31	0.11
NPAG Quarry	0.15	---
Waste Rock Platform area	0.09	---
Footprint of the Contact Water Collection System	0.20	---
WRTSF	0.70	---
BJ 3.10 at weir	6.55	0.43
BJ 2.62	7.33	0.69
BJ 1.74	8.63	0.81

3.3.4 Summary of Three Reservoir Model Coefficients

A summary of the Birkenes model coefficients necessary to populate and calibrate the runoff models developed in GoldSim is provided in Table 3-2. The temperature-dependent glacier melt coefficients used in the WBM are also reported in this table.

Table 3-2:
Summary of Birkenes Model Coefficients for BJ 3.10 Calibration

Metric	Value
Area (km^2)	6.5
$A_{initial}$ (mm)	100
A_{min} (mm)	300
B_{max} (mm)	1,500
B_{min} (mm)	300
$B_{initial}$ (mm)	250
K_A (mm/mm/d)[1]	0.3
K_B (mm/mm/d)[1]	0.04
K_{BASE} (mm/mm/d)[1]	0.001
K_e (mm/°C/d)	0.2
M_{coeff1} (mm/°C/d)[2]	4
M_{coeff2} (mm/°C/d)[3]	6
M_{coeff3} (mm/°C/d)[4]	5

[1]mm/mm/d indicates mm of runoff per mm of reservoir volume per day
[2]Melt coefficient for T < 5°C; [3]Melt coefficient for T < 15°C; [4]Melt coefficient – glacier

3.3.5 Summary of Model Performance for the Calibration Period (2015-2021)

Measured data and modelled results for the calibration period were assessed using metrics such as comparisons of measured and modelled averages, the Root Mean Square Error (RMSE), the Nash-Sutcliffe efficiency coefficient (NSE) and log-NSE coefficient (Table 3-3). In addition to a visual comparison of modelled and measured values (Figure 3-8; Figure 3-9), these metrics allowed the skill of the model at replicating measured conditions to be objectively quantified. At a high level, measured and modelled streamflow statistics such as mean, median, P5 (5th percentile) and P95 (95th percentile), compare very favourably for the calibration period at BJ 3.10 (Table 3-3). Similarly, the RMSE metric indicates close correspondence between modelled and measured conditions.

The Nash Sutcliffe Efficiency Coefficient (NSE) is commonly used to assess the predictive power of hydrological models. An NSE value of 1.0 means that a perfect match has been made between the modelled output and the measured data, whereas a value of 0 indicates that the predictions are only as accurate as the mean of the measured data (Moriasi *et al.* 2007). Furthermore, NSE values that exceed 0.70 are viewed by Moriasi and coauthors as being a very good calibration. The NSE tends to overemphasize the errors in peak flows more than low flows because it is based on the square root of the deviations between measured and modelled values. To account for this, a logarithmic transformation is run on the modelled and measured values prior to calculating the NSE, which results in more weight being placed on the low flows.

Table 3-3:
Summary of Model Performance for the Calibration Period (2015-2021), BJ 3.10

Performance Measure	BJ 3.10_Measured	BJ 3.10_Weir.GoldSim	Comment
Mean (m^3/s)	0.417	0.403	Values compare within 5%
Median (m^3/s)	0.211	0.234	
P5 (m^3/s)	0.054	0.056	
P95 (m^3/s)	1.243	1.195	
RMSE	0.195		---
NSE	0.79		Very good[1]
log NSE	0.86		Very good[1]
RSR	0.46		Very good[1]

[1]Qualitative descriptions based on the performance classifications presented in Moriasi *et al*. (2007) - Model Evaluation Guidelines for Systematic Quantification of Accuracy in Watershed Simulations.

With respect to the modeling effort undertaken for Brucejack Mine, the calibration period shows NSE and log-NSE values are 0.78 and 0.89, respectively, at BJ 3.10 (Table 3-3). Further afield, NSE (0.75) and log-NSE (0.81) values were slightly lower at BJ 1.74, but still very satisfactory. As a final check on model performance at BJ 3.10, the RMSE-

observations standard deviation ratio (RSR) was also computed. RSR is calculated as the ratio of the RMSE and the standard deviation of measured data. The computed RSR for the calibration period (*i.e.*, 0.46) was also indicative of very strong match between measured data and modelled results. In summary, a watershed model has been developed for application within the Brucejack Creek watershed, and the robust calibration results provide confidence that sub-area runoff models within the larger model domain, are based on a strong foundation of measurement and modelling.

Figure 3-8: Comparison of measured versus modelled streamflow at BJ 3.10 for the calibration period of 2015-2021 as time series (upper panel) and flow duration curve (lower panel) plots.

Figure 3-9: Comparison of measured versus modelled streamflow at BJ 1.74 for the calibration period of 2015-2021 as time series (upper panel) and flow duration curve (lower panel) plots.

3.4 Underground Mine Sub-model

3.4.1 Overview

The water balance of the Underground Mine is depicted in Figure 3-10. Main concepts/components shown on the figure include:

- The pumping of freshwater from surface to the 'waterbox', which is situated in the underground mine. The waterbox reservoir is situated in the lower right-hand corner of Figure 3-10. Stored water within the waterbox is used to support drilling and dust suppression activities, as required.
- Pictured immediately above the waterbox reservoir (Figure 3-10) are Input and Function elements that handle calculations related to underground water use and the re-cycling of used water back to the Underground Mine Sump – which is positioned at the bottom left corner of the schematic.
- The accounting of any paste backfill, and any leakage from placed material, is handled by Input and Function elements (shown Figure 3-10, upper-middle of plot).
- In the upper left of Figure 3-10, time series elements and an expression handle the read-in of measured (pre-2022) and modelled GW (2022 and forward) inflows that report through the underground mine to the mine sump. Measured and modelled GW fluxes were shown previously in Section 2 (see Figure 2-10).
- Finally, a Stock element (reservoir) is used to represent the UG_Mine_Sump. Within this element is functionality to control which inputs report to the sump, and how material is exported from the system.

Figure 3-10: GoldSim wire diagram depicting the water balance of the Underground Mine.

3.4.2 Model Inputs and Assumptions, Underground Mine

Below is a list of assumptions relevant to the Underground Mine Sub-model:

- For the pre-2022 time period, measured data that represent flow from the freshwater tank, to the underground waterbox, are read into the WBM model (Figure 3-11).
- Flows to the waterbox are represented in the model using a stochastic Input element, which produces a daily varying flux that closely mimics patterns evident in the measured record.
    - In the 2020 WBM (Lorax, 2020), below ground water used for dust suppression and drilling was assumed to increase linearly to maximum values of approximately 50 m^3/hr and were then held constant for the period of Operations.
    - However, following inspection of measured records for below ground water use (Figure 2-12, upper panel), the 2022 WBM update allows below ground water use to increase linearly to values on the order of 80 m^3/hr by 2025, remaining constant thereafter.
- While the assumed rate of below ground use was increased in the 2022 WBM, it is important to note that most of this water is assumed to recycle back to mine sumps with a 95% efficiency.
- As a Base Case, the WBM assumes paste backfill is 60% solids by mass, with water comprising the residual mass.
- The WBM assumes that 2.5% of the paste backfill water content, seeps or leaks, and reports to the main sump. Note that this same assumption was applied in previous versions of the WBM (BGC, 2017c).
- Measured GW inflow (pre-2022), modelled GW inflow, dust suppression/drill waters and paste leakage are assumed to report to the Main Sump. When the Main Sump is full, and to prevent overflow, all excess water is pumped to surface and directed to the clarifier and WTP.

Figure 3-11: Measured data for a representative year showing dominant flows of the Underground Mine water balance, including total flow to sump, groundwater recharge to sump and flows to the 'waterbox' which are used to support drilling and dust suppression activities in the mine.

3.4.2.1 Closure and Post-Closure

Pretium (2023) describes the rehabilitation activities associated with closure of the underground mine, including removal of pumping, electrical and ventilation systems and reclamation activities at portals. As part of the rehabilitation measures, five plugs will be placed in the underground mine – two situated in the WZ and three in the VOK Zone. Further details supporting the rationale and location of plugs is provided in Lorax (2023a).

Closure water balance modelling in this study considers two scenarios: Passive Fill Scenario and Accelerated Fill Scenario. Relevant WBM considerations and assumptions are outlined below for these two scenarios.

Passive Fill Scenario

- Following cessation of ore processing, the mine will be allowed to fill passively.
- For this scenario, the WBM assumes no pumping of water from the FWT to the waterbox, after mining ceases in December 2029. Similarly, the model assumes that pumping of sump waters from depth in the mine, to surface, ceases as well.

- The mine void is estimated to be 1.54 Mm^3 and the Passive Fill scenario ends when the mine pool is fully developed, maximum water elevation is reached, and seepage flowpaths from the underground mine to the receiving environment establish.

Accelerated Fill Scenario

- Following cessation of ore processing, pumping of the mine sump will stop and groundwater recharge will begin to fill the mine void.
- To shorten the fill time, the Accelerated Fill scenario assumes permitted reclaim of 70 m^3/hr is directed to the underground mine. This diversion of reclaim water is consistent with Pretium's existing water use licence and equates to roughly 50,000 m^3/mon of surface water, which in addition to groundwater recharge, shortens the fill duration under this scenario.
- Diversion of reclaim water specific to this scenario is proposed to begin Jan 2030 and occur for four months, until the end of April. Consistent with Operations phase water management, the proposed point of diversion for reclaim allowances is Brucejack Creek at monitoring location BJ 3.10.
- The Accelerated Fill scenario also assumes that up to 20% of the natural flow of Brucejack Creek at BJ 3.10 is diverted to the underground mine over the course of May, June, July and August 2030.
    - The diversion is proposed as a 'percentage of natural flow' in order to minimize any alteration to the flow regime of Brucejack Creek and any effects on aquatic biota.
    - Streamflow monitoring data for BJ 3.10 indicates the proposed diversion equates, on average, to a volume of 1.66 Mm^3.
- Under this scenario, a continued re-circulation of water between the mine pool and WTP, is proposed, with treated effluent from the WTP directed back to the underground mine (Figure 3-12). Maximum rate of treatment at the WTP is 10,000 m^3/day (or 417 m^3/hr), which expressed as a monthly volume is approximately 300,000 m^3. This means that several 'treatments' of the mine pool volume are possible over the course of the Accelerated Fill scenario.

Figure 3-12: Conceptual illustration of an Accelerated Fill scenario with circulation between the underground mine and WTP.

3.5 Surface Water Management System

The surface water management system for the mine site includes two non-contact water diversion channels, a contact water collection system (CWCS) and the contact water pond (CWP). The surface water management system is described further in the sections below, while highlighting relevant WBM model inputs and assumptions related to it.

3.5.1 Non-Contact Water Diversions

Diversion channels at the mine site divert surface runoff around surface infrastructure and temporary waste rock storage areas (Figure 3-13). Diverted water discharges either to the WRTSF via the Johnson Creek (East) Diversion Channel or downstream to Brucejack Creek below the WRTSF via the Camp Creek (West) Diversion Channel.

3.5.2 Contact Water Collection System

Contact water at the mine site is defined as water contacting PAG rock exposed through mining or related rock excavation activities. Three main sources of contact water are relevant at the mine site:

- Contact water resulting from placement of waste rock in the WRTSF.
- Groundwater seepage within the underground mine contacting exposed surfaces then reporting to sumps. These waters are pumped to surface and directed to the WTP.
- Surface waters produced following contact with PAG bedrock exposures at the mine site (*e.g.*, pads associated with the mill and lower camp).

With respect to surface contact water, a network of interception ditches, pipelines, sumps, collection areas and pumps, are in place at the mine site to manage these flows (Figure 3-13).

3.5.3 Flow Measurements for the CWCS

Using a modified mass balance equation (*i.e.*, CWCS = ΔCWP Storage + CWP Outflow – WTP Inflows), the CWP monitoring dataset was used to back-calculate CWCS flow rates and runoff volumes, at daily frequency. An estimated flow series for the CWCS, spanning the period July 2017 to December 2021, is shown in Figure 3-14. For comparison purposes, the CWCS flow series is expressed as a runoff depth, in units mm, which allows for efficient comparison to measured runoff depths at BJ 3.10. Noting that runoff data for the entirety of 2017-2021 are shown in the plot for BJ 3.10, several observations are apparent from a data comparison of runoff depths at CWCS and BJ 3.10:

- The two flow records show strong similarities in terms of the onset of freshet runoff conditions in May. Runoff response to summer storms and rainfall events is also apparent in both flow records.
- The two flow records share a pattern of low, and generally constant, runoff depth through winter. However, a notable difference in Figure 3-14 is that CWCS runoff depths are lower in magnitude than measured depths at BJ 3.10 through the winter.
- A second major difference is these runoff data indicate total freshet runoff at the CWCS is much lower that at BJ 3.10. This is not surprising as the bulk of the freshet hydrograph is attributed to melting of snow and efforts are made at the mine site each winter to remove snow from roads, pads and roofs of buildings, such that access is efficient and safety requirements are met. Furthermore, the larger WRTSF watershed includes snowmelt contributions over a wider range of elevations that are assumed to sustain higher runoff depths at the outlet during freshet.

These observations are relevant to Section 3.5.2 below which is where inputs and assumptions relevant to the set-up of the CWCS sub-model, are discussed.

A GoldSim container is shown in Figure 3-3 for the CWCS. Within the container, a three-reservoir runoff model is used to compute contact water collection system runoff. Surface runoff captured by the CWCS is directed to the Contact Water Pond (CWP), where volumes of water may be stored for later use or directed to treatment (WTP) for discharge to the WRTSF. Discussed later in Section 3.6, the CWP and WTP elements of the GoldSim WBM are located within the CWP_WTP_mill container (Figure 3-3).

Figure 3-14: Time series data showing CWCS flow to the CWP, August 2017 to December 2021.

3.5.4 Summary of Inputs and Assumptions for the Contact Water Collection System

To achieve a reasonable visual calibration of the CWCS runoff model, the following steps and assumptions are applied in the WBM:

- A three-reservoir model was populated with the calibration coefficients and input values indicated in Table 3-4.
- An area of 20 ha is assigned in the model to convert CWCS runoff depths to an equivalent flow rate (Table 3-4).
- Within the rainfall/snowfall scheme of the CWCS runoff model, a data scalar was added to reduce snowpack within the CWCS to 60% of the expected value. This assumption is much like the value used previously by BGC whereby snowpack was reduced 50% for their CWCS runoff model (BGC, 2017c).
- As per BGC (2017c), only a portion of the total runoff generated by the footprint of the CWCS is assumed to report to the CWP. Previously, BGC assumed 75% of the runoff generated by the CWCS reports to the CWP (*i.e.*, 25% of the runoff reports passively to either the WRTSF or Brucejack Creek below BJ 3.10). However, to achieve a suitable runoff model calibration, it was necessary to refine this assumption and assume 60% of total CWCS runoff reports to the CWP.

- A mapping analysis was completed to apportion the 40% losses from the CWCS footprint to either the WRTSF or Brucejack Creek. A splitter element is used in the GoldSim model to direct the CWCS losses to the WRTSF or Brucejack Creek in proportions 0.6 and 0.4, respectively.
- At closure, the CWCS will be reclaimed and the current plan is for the CWP to remain, fill to the level of the current spillway, then discharge freely to the WRTSF. These activities are scheduled to occur in the summer and autumn of 2030. During the closure and post-closure phase, total runoff from the CWCS footprint is directed to the WRTSF and Brucejack Creek in proportions 0.6 and 0.4, respectively.

Table 3-4:
Summary of Birkenes Model Coefficients for CWCS

Metric	Value
Area (ha)	20
$A_{initial}$ (mm)	100
A_{min} (mm)	100
B_{max} (mm)	700
B_{min} (mm)	500
$B_{initial}$ (mm)	600
K_A (mm/mm/d)	0.09
K_B (mm/mm/d)	0.3
K_{BASE} (mm/mm/d)	0.3
K_e (mm/C/d)	0.2
M_{coeff1} (mm/C/d)[1]	4
M_{coeff2} (mm/C/d)[2]	6

[1]Melt coefficient for T < 5°C; [2]Melt coefficient for T < 15°C

3.5.5 Contact Water Pond

The CWP is situated adjacent the mill complex (Figure 3-13) and has been in service since 2017. Relevant technical details for the facility are summarized in design, construction and engineering reports prepared by BGC Engineering (refer to BGC, 2013; BGC, 2017a).

Maximum storage in the CWP is assumed in the WBM to be 50,000 m^3. Each autumn, additional water (up to 40,000 m^3) resides in the pond to minimize the likelihood of mill process water deficit by late winter (Pretium, 2020b). Stored water in the CWP is directed to the clarifier and WTP when required, where it is treated, then used for ore processing, which diminishes CWP supply, by March. In contrast, the CWP is managed at a low

volume (~15,000 m^3) during freshet and summer, such that adequate storage is available to accommodate flood flows. To maintain a constant volume within the CWP during freshet and summer, excess water in the CWP is directed to the WTP, and treated effluent may be used in the mill, or discharged to the WRTSF should mill requirements be fully met. The patterns of CWP stage/volume described above are clearly illustrated in monitoring data for the facility (Figure 3-15).

Figure 3-15: Time series showing CWP volume (blue) for the period 2017-2022. The dashed green line indicates the maximum operational storage capacity of the pond, whereas the dashed orange line indicates the volume above which generates leakage from the facility.

3.5.6 Leakage Losses from the CWP to WRTSF

A leakage study was completed by BGC in 2017 to quantify the magnitude of losses from the facility (BGC, 2017a). A principal finding from the study is that stage-dependent (*i.e.*, when CWP storage exceeds ~15,000 m^3) contact water may seep from the CWP toward the WRTSF. The study reports three potential rates of leakage, a low case, a high case and a geometric mean case, each case differing in predicted leakage by approximately an order of magnitude. The WBM is configured to account for leakage losses from the CWP at rates equivalent to geometric mean case predictions (Figure 3-16) which equates to seepage losses on the order of 1 m^3/day.

Figure 3-16: Example leakage loss estimates of the CWP for the geometric mean case.

3.6 CWP, WTP and Mill Water Balance

3.6.1 Overview

A GoldSim sub-model illustrating the water balance of the CWP, WTP and mill, is shown in Figure 3-17. The layout of the sub-model is defined by eight interconnected reservoirs. Reservoirs are included to represent the: CWP, clarifier, WTP, TWT, FWT, and the mill, the latter which is described using three pools (*i.e.*, Mill, Process_Return and Process_Water _Tank). A number of Input and Expression elements are used in conjunction with the identified pools to resolve the water balance for this important aspect of the site-wide WBM.

GoldSim functionality shown in the upper-left area of Figure 3-17 handles interactions between the CWP, clarifier, WTP and TWT. To elaborate, three sources of water (CWP, underground dewatering and process water return flow) report to the clarifier, with representative measured data shown in Figure 3-18. The clarifier removes solid particulates or suspended solids from influent. Clarifier outflow reports to the WTP, and from the WTP, treated effluent may be directed in the WBM to one of two places: 1) the FWT, which is a critical point of supply for the underground mine (waterbox) and the mill; or 2) toward the TWT. For treated effluent directed to the TWT, there is logic in the model to direct volumes

back to the CWP if volume is below capacity, or alternatively, to the WRTSF (Figure 3-19), if supply requirements are being fully met. Model logic for the CWP-WTP-TWT circuit is controlled by two 'Selectors' shown in Figure 3-17, as well as a look-up table. Note that Figure 3-17 also shows Input and Expression elements that are connected to the clarifier and WTP. These elements of the WBM handle calculations related to clarifier Underflow and WTP waste from the Actiflo (plus polishing) circuit.

Pictured middle-lower on Figure 3-17 is the mill circuit. Here, the mill 'pulls' water from the FWT to meet water demands for ore processing. Volumes within the FWT are maintained by WTP effluent and any reclaim water volumes which are drawn from the BJ 3.10 weir, noting that Pretium is currently permitted to withdraw water from the BJ 3.10 weir all months of the year at 70 m^3/hr. With respect to mill demand calculations (*i.e.*, for concentrate, tailings and paste backfill), these are computed in the containers shown at the right-hand side of Figure 3-17. The WBM is configured such that water supply entering the mill generally meets or exceeds true demand. In this regard, excess water reports to the process water tank (PWT). The majority of flow from the PWT is directed back to the mill, whereas a smaller flow is directed from the tank back to the clarifier-WTP.

Figure 3-17: Overview schematic of the CWP-WTP-Mill sub-model

Figure 3-18: Time series showing representative measured data for the clarifier

Figure 3-19: Representative time series showing discharge of treated effluent from the TWT to the Brucejack WRTSF. The blue line shows measured data, whereas a 7-day running mean of the measured data is shown in red

3.6.2 Inputs and Assumptions for the CWP-WTP-Mill Sub-model

The bullet points below summarize relevant water balance assumptions for the CWP-WTP-Mill sub-model:

- The CWP is assumed to be 50,000 m^3. For LOM years 2020-2029, the WBM assumes the CWP will be managed at low volume (~15,000 m^3) during spring, summer and autumn, and a much higher volume (up to 40,000 m^3) during the winter (*e.g.*, November through March).
- Any captured runoff from the CWCS is assumed to report to the CWP. Any stage-dependent leakage from the CWP is computed by the WBM for the geometric mean case.
- The clarifier pool is configured to receive daily inputs from three sources: any underground mine dewatering flow; CWP 'overflow', which are in essence pumped flows from the CWP; and PWT overflow.
- A stochastic Input element is used in GoldSim to compute clarifier underflow. Clarifier underflow is directed to the mill and set a mean value of 12 m^3/hr. The purpose of the stochastic Input element calculation is used to create GoldSim output for this term, an approach which aims to match the daily variability about the mean value of the measured record.
- The WBM assumes a target minimum WTP inflow rate of 180 m^3/hr, whereas the maximum allowable flow rate for the WTP is set at 417 m^3/hr.
- Actiflo waste volumes are computed using measured data that define a relationship between waste volumes and WTP inflow rate (Figure 3-20). Using these relationships and modelled WTP inflow rates as a predictor, associated waste volumes are computed in the WBM using a GoldSim Input element.
- The WBM assumes the TWT is 63 m^3. Should surplus water be reporting to the WTP, overflow (or bypass) can be directed toward this tank. From here, model logic is in place to direct WTP overflow to either the CWP, if volume exists in the pond, or the WRTSF.
- The WBM assumes the FWT is 667 m^3. The FWT is the water supply for the mine site fire suppression system; therefore, it is essential this tank is near capacity at all times. The WBM contains code to ensure the tank remains full, as a priority.

Figure 3-20: Measured waste and WTP inflow data for Brucejack Mine. Data in the upper panel illustrate the relationship between Actiflo waste and WTP inflow, whereas the lower plot shows the linkage between Actiflo polish waste and WTP inflow.

Note: The shaded areas above are intended to identify 'areas' that encompasses the bulk of the measured data. Stochastic input tools in GoldSim, using WTP inflow as a predictor, were used to estimate waste volumes predominantly falling within the boundaries of the shaded areas.

- The FWT receives effluent from the WTP, as well as any reclaim diversion volumes taken from BJ 3.10 weir. Pretium is permitted to divert from BJ 3.10 weir at a flow rate of 70 m^3/hr or a monthly volume of approximately 50,000 m^3. These flow rates are encoded into the WBM.
- As a general target, the WBM seeks to achieve balanced or constant flows on the order of 180-200 m^3/hr for the FWT. This equates to a maximum of 4,300 m^3/day, which experience shows is the upper limit for water demands at the mine site for ore processing at 3,800 tpd.
    - In 2022, the water balance model code was updated to allow additional flow to report to the FWT as demand for water increases for the 4950 tpd case.
- The PWT is assumed to have a volume of 352 m^3. Recycling of PWT volumes back to the mill is configured in the WBM at 330 m^3/hr. Furthermore, PWT pumping to the clarifier is set at 52 m^3/hr.
- Water balance model assumptions relevant to ore processing calculations are aligned with the approach of BGC (2017c) with details summarized in Table 3-5.

Table 3-5:
Ore Processing Assumptions – Brucejack WBM, Base Case

WBM Component	Base Case Assumption
Mill feed	As dictated by the 4950 tpd Joint Application Mine Plan, resolved monthly through 2029
Ore moisture	3% (by weight)
Tailings[1]	60% solids (by weight)
Paste backfill	60% solids (by weight)
Concentrate[2]	5.07% of mill feed at 93% solids (by weight)
U/G mine water supply[3]	Increase linearly with mill feed to a maximum of 80 m^3/hr
Flow target, Freshwater Tank	180-200 m^3/hr
Flow target, Process Water Tank to Mill	330 m^3/hr
Flow target, Process Water Tank to Clarifier	51 m^3/hr
Clarifier Underflow	12 m^3/hr
STP Effluent	90 m^3/day
WTP, Maximum treatment rate	417 m^3/hr or 10,000 m^3/day
Reclaim diversion, maximum rate	70 m^3/hr

1 A value of 55% solids (by weight) was assumed for 2017-2020.
2 An estimate of concentrate equating to 6.5% of mill feed at 93% solids (by weight) assumed for 2017-2021.
3 Informed by measured data for the period July 2017 to December 2021.

3.6.3 CWP-WTP-Mill Sub-model Calibration

Because there is robust operational monitoring data for the mine site, comparisons of measured data and modelled results were made for a 2018-2022 'calibration period'. The purpose of the evaluation was to ensure the model was replicating patterns and magnitudes of flow/volumes at key locations within the CWP-WTP-Mill sub-model. The focus of the calibration effort was on the following measured and modelled terms: CWP volume; any reclaim diversion from BJ 3.10 weir; the WTP pumping signature to the TWT; recycling of water from the TWT to the CWP; and finally, overflow from the TWT to the WRTSF.

Four figures are presented below in an effort to summarize the findings of the sub-model calibration (Figure 3-21, Figure 3-22, Figure 3-23 and Figure 3-24). For the period July 2017 to December 2021, Figure 3-21 illustrates the WBM provides a reliable replication of stored volumes within the CWP. Measured CWP volumes are shown in the figure by the blue line and modelled data are red, and results show model skill in handling CWP volume over several winter and ice-free periods. Measured reclaim (grey) and modelled reclaim (green) are also shown in Figure 3-21 to illustrate WBM handling of these diversions from BJ 3.10 weir to the FWT.

Measured and modelled data comparisons also provide the opportunity to confirm the model is handling WTP overflow correctly, and whether pumping of effluent to the TWT, and pumping from there to either the CWP or the WRTSF, is handled reliably in terms pattern/magnitude of flow rates. Key results are Figure 3-22 (WTP overflow to TWT), Figure 3-23 (TWT to CWP) and Figure 3-24 (TWT to WRTSF). Based on a visual inspection of these results it is concluded that the WBM model reliably represents water management related to the CWP, WTP and mill.

Figure 3-21: Comparison of measured and modelled volumes at CWP (upper panel) and measured and modelled reclaim flow rates (lower panel for the period 2017 through 2021.

Figure 3-22: Comparison of measured and modelled flow series for WTP overflow directed to the TWT (2018-2021).

Figure 3-23: Comparison of measured and modelled flow series for TWT pumping to the CWP (2018-2021).

Figure 3-24: Comprison of measured and modelled flow series for TWT overflow to the WRTSF (2018-2021).

3.7 Sewage Treatment Plant

The WBM accounts for the discharge of effluent from the Brucejack Mine sewage treatment plant (STP) to the Brucejack WRTSF (Figure 3-3).

A schematic showing the Input and Function elements used to compute STP flows in the GoldSim WBM is provided (Figure 3-25, upper panel). An STP Schedule is encoded in the model, which serves to turn the STP on or off, based on user adjusted dates. The WBM reads in measured STP data for the pre-2022 simulation period. For the period January 2022 to early closure, the model derives flows that are reflective of recent monitoring data, which equates to an average of 90 m^3/day (Figure 3-25, lower panel). STP discharges are modelled forward using the stochastic Input element in GoldSim, which introduces variability about the mean value of 90 m^3/day and provides modelled output that matches recent observations very well.

Figure 3-25: Schematic showing GoldSim wire diagram (upper panel) and results from the Sewage Treatment Plant (STP) container (lower panel).

3.8 Brucejack WRTSF

Figure 3-26 provides an overview of the WRTSF container. The WRTSF pool, situated centre-left in the schematic, is a critical model element in the diagram. The WRTSF is a principal point of discharge at the mine site, and accordingly, 11 main inflow terms and three outflow terms are controlled by this WBM element (Table 3-6).

Model inputs and assumptions for the Brucejack WRTSF are described further in the sections below.

Figure 3-26: GoldSim schematic of the Brucejack WRTSF container.

3.8.1 Precipitation and Evaporation

At a daily time-step, precipitation and evaporation data from the Climate container are used to represent meteoric inputs that report to and from the WRTSF. Precipitation and evaporation depths are converted in the WBM to daily volumes and flow rates based on a scaling procedure using WRTSF area, which is assumed to be 70 ha (Table 3-1).

3.8.2 Placement of Waste Rock and Tailings in WRTSF

Tailings and waste rock placement in the WRTSF displaces water and reduces the volume of the storage facility. Further, pore spaces in the placed material consume WRTSF storage, as material settles to the bottom of the facility. Model code is in place to handle reductions in WRTSF volume owing to the placement of waste rock and tailings solids in the WRTSF. Calculations are handled in the GoldSim model using the assumptions and approach outlined in BGC (2017c).

Table 3-6:
Summary of Inflows and Outflow Terms for the Brucejack WRTSF

	ID	Term	Description
Inflows	1	Direct_P_to_TSF	This WBM term tracks rainfall and snowmelt flux to the WRTSF surface
	2	Final_Q_toTSF_Bgrd	This WBM term accounts for background runoff to the WRTSF
	3	Final_Q_Quarry	This term represents the runoff volumes for the NPAG quarry
	4	Final Q_WR_Pad	This model term tracks runoff volumes from the waste rock platform to the WRTSF
	5	Treated_Water_Tank.Overflow	The discharge of treated effluent from the TWT to the WRTSF are tracked through this term
	6	Tails_Water_to_TSF	This WBM term accounts for tailings slurry water to the WRTSF
	7	Stochastic STP_to_TSF	Any discharges from the STP are accounted for in the WRTSF by this model term.
	8	WTP_Actiflow_to TSF	This term tracks WTP Actiflo wastes that are directed to the WRTSF
	9 a,b	CWCS losses to TSF	CWCS losses to the WRTSF are tracked through two flow terms (*i.e.*, direct runoff, system losses)
	10	CWP.CWP_Leakage	Any stage-dependent leakage from the CWP reports to the WRTSF via this term.
Outflows	1	TSF_Evap	This term represents the evaporative flux from the WRTSF surface
	2	Loss_to_Voids	Loss of WRTSF water to tailings and waste rock voids are accounted for by this model term
	3	Brucejack_TSF.overflow	This WBM term tracks any WRTSF outlet overflow to Brucejack Creek

4. Water Balance Model Results

This section of the report presents an accounting of WBM conditions for the operations, closure, and post-closure phases of the Brucejack Mine. Prior to any technical discussion, Section 4.1 provides a high-level summary and discussion of the site-wide water balance for the mine site.

4.1 Overview

A site-wide water balance model was originally constructed for Brucejack Mine in Excel using a monthly time-step (BGC, 2017a,b). The water balance model was updated in 2020 for the 5 Year Plan (Lorax, 2020), and again in 2022, to support preparation of the 4950 tpd Joint Application. Since 2020, water balance updates for the mine site have been completed using GoldSim modeling software, the same software platform which is used to run the Brucejack Mine water quality model.

4.1.1 Operations (2022-2029)

Generalized flow schematics of the mine site water balance for operations and closure/post-closure are shown for reference in Figure 4-1 and Figure 4-2 respectively. During operations, main sources of water for ore processing at the Brucejack Mine include: 1) water that is recycled from the mill process; 2) water conveyed by contact water ditches and surface sumps and reports to the CWP; 3) water that reports to sumps of the underground mine and is pumped to surface; and 4) permitted water withdrawals that are sourced from Brucejack Creek adjacent the BJ 3.10 weir.

Water recycled from the mill process or withdrawn from CWP storage is first treated prior to being used in the mill. In concept, surplus treated water may be discharged to Brucejack WRTSF when mill water requirements are fully met or it is necessary to manage pond volumes at a certain level. Alternatively, surplus treated water may be managed back to the CWP should there be available storage in the pond. Operational water data collected between 2018 and present indicates that discharges of treated effluent to the WRTSF are necessary between May and October because the majority of annual runoff is realized during these months, and accordingly, water surpluses are encountered at the mine site in general.

Water that reports to the underground mine is captured in sumps and then pumped to surface (Figure 4-1). Like water sourced from the CWP, sump water is treated prior to being used in the mill or discharged to the WRTSF when freshwater supply exceeds mill water demand. A major component of underground sump water is groundwater recharge

that daylights in the mine due to dewatering activities. Groundwater inflows are seasonally variable, with values being lower in winter (*e.g.,* February, March), and notable that recharge rates to the mine are predicted to increase with time as the footprint below ground increases with the progression of mining (refer again to Figure 2-10). In addition to groundwater recharge, water from the FWT in the mill building is also directed below ground to support mining activities, such as drilling and dust suppression. Like groundwater recharge, the majority of this circulated water reports back to underground sumps and is pumped to surface for treatment, use in the mill, or release to the WRTSF.

Mill demands/surpluses and underground mine water requirements for the 2022-2029 period, which includes 4950 tpd throughput between 2025 and 2029, are summarized as follows:

- Concentrate: The model assumes approximately 5% of total production reports to an off-site facility as concentrate for secondary processing in a slurry of 93% solids by weight. The average concentrate demand is estimated by the model to be 0.7 m^3/hr (or 17 m^3/d) for the 2022-2029 period.
- Tailings to Brucejack WRTSF: For 2022–2029, the model assumes 2,656 tpd (approximately 60% of total tailings production), on average, will be deposited at depth in Brucejack WRTSF in a slurry of 60% solids by weight (~71 m^3/hr of slurry water).
- Paste Backfill: The model assumes 1,704 tpd will be deposited in the underground mine in a cemented backfill paste of 60% solids by weight (~47 m^3/hr of slurry water).
- Underground (mine supply) water: based on operational water monitoring data collected between 2017 and present, water demand within the underground mine has increased linearly over time to levels on the order of 50-60 m^3/hr in 2022. The WBM assumes below ground water use is approximately 80 m^3/hr after 4950 tpd production is reached in 2025.

In summary, for operations (2022-2029) the site-wide water balance model provides an accounting of project activities at the spatial scale of the mine site (*i.e.*, the tracking of flows between the FWT, the underground mine, the CWP, the WTP, the mill, and the WRTSF), and also tracks background and surface water flows from the headwaters of the Brucejack WRTSF watershed, downstream to the BJ 1.74 monitoring location, which is well downstream of the Brucejack WRTSF. In addition, the water balance model tracks volumes of water and mine waste that report to Brucejack WRTSF over the period of active mining. For example, the model accounts for the displacement of WRTSF volume resulting

from tailings and waste rock deposition and losses of WRTSF water to tailings voids upon placement in the WRTSF.

4.1.2 Closure Filling Scenarios and Post-closure

Several closure/filling scenarios are contemplated in the water balance model (*e.g.*, passive fill versus active with treatment) with detailed results for a Base Case and sensitivity scenarios presented in Section 4.5. For post-closure, the WBM fully accounts for any background/non-contact runoff generated within the BJ 3.10, BJ 2.62 and BJ 1.74 watersheds (Figure 4-2). The model assumes the mine site, including the mill, access roads and related laydowns/pads, are reclaimed, with any runoff from these footprints assumed to report passively to either Brucejack WRTSF or Brucejack Creek below the BJ 3.10 weir.

Post-closure seepage flow from the underground mine to Brucejack Creek is depicted on Figure 4-2. Contact water fluxes generated from the flooded mine are simulated to range seasonally between 10.4 L/s and 22.9 L/s, averaging 14.9 L/s annually. This is approximately 5 L/s higher than what was predicted by the 3,800 tpd model and is attributed to expansion of the mine extents as listed in the third bullet. Approximately 95% of contact water reports to Brucejack Creek above BJ-2.62, of which approximately 10% reports to the WRTSF. A further 4% of contact water reports to Brucejack Creek between BJ-2.62 and BJ-1.74. About 1% of contact water reports below BJ-1.74.

Figure 4-1: Water balance summary for LOM operations (2022-2029) – Base Case (Average Climate Conditions)

Figure 4-2: Water balance summary for closure and post-closure (2030-2050) – Base Case (Average Climate Conditions)

4.2 Operations (2022-2029)

4.2.1 Underground Mine

Representative output from the Underground Mine sub-model is shown in Figure 4-3. Dominant fluxes in the underground mine water balance are groundwater recharge fluxes and pumping flows (to surface) associated with the mine sump (Figure 4-3). In contrast, paste leakage flows are very minor and water balance flows associated with dust suppression and drilling in the underground are intermediate in magnitude.

It is noteworthy that pumped volumes to surface carry a seasonal signature (*i.e.*, sumps flows are lower in magnitude in winter months that for spring, summer and autumn periods). Operational experience from 2017-2021 indicates mine dewatering flows, along with diversions from reclaim and the CWP, are required to meet water demands at the FWT and mill, through the winter period. Measured data confirms the annual minima for GW inflow to the mine was in the range 20-35 m^3/hr for the 2017-2021 period. However, annual minima are predicted to increase to 80-100 m^3/hr by 2025, coinciding with 4950 tpd ore processing, and predicted to be higher still by end of mining in 2029 (*i.e.*, 110 m^3/hr). Owing to the increase over time, winter water scarcity is anticipated to lessen over LOM, assuming future winter minima show increases that are aligned with reported GW modelling results.

4.2.2 Contact Water Collection

Representative flows associated with the CWCS are shown in Figure 4-4. Recoverable contact runoff (red line) and CWCS losses (blue line) are shown as separate terms in the plot. Like mine dewatering flows, measured and modelled results for CWCS runoff results show strong seasonality. During freshet and following storm events, CWCS inflow rates to the CWP are estimated to range from 20-100 m^3/hr typically, although they may be much higher for short periods of time (*i.e.*, >140 m^3/hr) (Figure 4-4).

The CWP has a capacity of 50,000 m^3 and several days of runoff from the CWCS has the potential to change the volume of the facility quite readily. In contrast, CWCS inflow rates are very low (<1-2 m^3/hr) for extended periods of time in the winter. Thus, there is little, if any, potential for the CWCS to appreciably influence CWP volume under typical winter conditions.

Figure 4-3: Water balance of the Underground Mine for LOM.

Figure 4-4: Time series showing contact water collection system flow estimates for LOM. Contact water flows that are directed to the CWP are demarcated by the red line, whereas the CWCS loss term is shown by the blue line.

4.2.3 Contact Water Pond

Representative water balance results specific to the CWP are shown in Figure 4-5 (CWP volume, CWP pumping to WTP) and Figure 4-6 (CWP leakage). The results illustrate that modelled volumes within the CWP mimic patterns and trends evident in water monitoring data collected at the facility since July 2017. As a general strategy, CWP volumes are managed to a constant volume/level (~15,000 m^3) over the course of spring, summer and autumn, but higher in the winter (*e.g.*, 38,000-40,000 m^3). Low volumes are maintained during the open water period, since there are requirements to store design flood flows within the pond, when they arise. Excess water is intentionally stored in the pond through autumn, then used over the course of the winter, when additional water volumes may be needed.

To maintain a low (15,000 m^3) and constant volume in the CWP, any excess water at the facility is pumped to the WTP. Since the CWCS produces much of its annual runoff at freshet and following summer rainfall events, higher rates of pumping are necessary to manage inflow from the CWCS during these periods. Any leakage losses from the CWP are relatively minor compared to other terms that comprise the site-wide water balance (Figure 4-6). Rates of leakage are estimated at 0.7 m^3/day during the open water (ice-free) period, when CWP volumes are lowest on an annual basis (*i.e.,* on the order of 15,000 m^3). Rates of leakage from the CWP are roughly double (1.4 m^3/day) when volumes in the facility are at their annual maxima, over the course of the winter.

Figure 4-5: Results from the WBM showing CWP volume (measured and modelled) for LOM.

Figure 4-6: WBM estimates of CWP leakage for LOM.

A key finding of the study is that demand for water at the mill, does not result in the CWP being depleted for Base Case. To elaborate, the WBM is set up to 'draw' water into the mill from multiple sources, to meet mill water requirements. Sources of water for the mill include reclaim diversions from BJ 3.10 weir, pumping of below ground mine sump water to surface then directing it to the mill via the WTP, and drawing upon stored volumes in the CWP. WBM results can be audited to determine if instabilities occur at the mill in terms of water supply or whether the CWP was completely drained on account of water demand pressures. In summary, the Base Case model run returned stable and expected conditions

at the CWP – which is an early indicator that water demands at the mill may be met by the available supply and existing water management system for the 4950 tpd scenario.

4.2.4 Clarifier, WTP and Treated Water Tank

Representative model outputs are shown for the clarifier, WTP and TWT in Figure 4-7, Figure 4-8 and Figure 4-9. Data in Figure 4-7 confirm the main inputs to the clarifier, which are underground dewatering flows, pumped flows from the CWP and overflow from the PWT. Furthermore, the results confirm there is a seasonal signature at the clarifier, which is expected, since mine dewatering and CWCS runoff volumes show higher flows/volumes during freshet and open water months, compared to winter periods.

Clarifier overflow (Figure 4-7; red line) is directed to the WTP where effluent is partitioned to either the FWT or TWT (Figure 4-8). In this plot, WTP.Overflow (red line) designates flow directed to the FWT and WTP.Total_Outflow (blue line) represents pumping of treated water to the TWT. Representative inflow and outflow data for the TWT are shown in Figure 4-9 and demonstrate the accounting of water volumes to the tank (blue line), any pumping to the CWP (green line) and pumping of treated effluent to the Brucejack WRTSF (red line).

Figure 4-7: Summary of water balance results for the clarifier for LOM.

Figure 4-8: Summary of water balance results for the WTP for LOM.

Figure 4-9: Summary of water balance results for the TWT for LOM.

4.2.5 Reclaim Diversion from BJ 3.10 Weir

Relevant results from the WBM are shown to illustrate the magnitude and pattern of reclaim diversion from BJ 3.10 (Figure 4-10). Overall, the time series for the period 2017-2029 confirms the general strategy to divert at a maximum rate in the winter and shoulder periods of autumn and spring, followed by diversion at a lesser rate (*e.g.*, 30-50 m^3/hr) during ice-free months when water surpluses are evident.

Figure 4-10: Total reclaim request from BJ 3.10 weir over LOM.

4.2.6 Freshwater Tank

This section presents water balance outputs for the FWT, the tank that provides supply to the mine site fire suppression system, the underground mine and the mill. Diversions from the FWT, to the underground mine are scheduled to support drilling and dust suppression activities. A supply of freshwater is required at the mill to process ore.

With respect to the requirement to maintain the tank near capacity (*e.g.*, 85% full or more), WBM results demonstrate this can be readily achieved for LOM under a 4950 tpd scenario (Figure 4-11). Inflow and outflow data are summarized for LOM for the FWT (Figure 4-12). Plotted data show total inflow to the tank (green line), pumping from the tank to the UG Mine (or waterbox, blue line) and tank overflow (pink line), which is the freshwater supply to the mill. Accordingly, a continuous supply of water is maintained at the FWT under Base Case, with mill supply being on the order of 150-220 m^3/hr over LOM.

Similar to discussion for the CWP (refer to Section 4.4.3), a key finding of the study is that demand for water at the mill does not result in depletion, or flow irregularities, at the FWT under Base Case (Table 3-5). In summary, the Base Case model run returned stable and expected conditions at the FWT – which is an indicator that mine site water demands are being met by the available supply and model assumptions which describe the Brucejack Mine water management system.

Figure 4-11: Time series showing FW Tank volume over LOM.

Figure 4-12: Time series showing inflow and outflows from the FWT over LOM.

4.2.7 Water Demand and Ore Processing

Water balance plots are presented in this section for mill surpluses and demands, including ore moisture, water demand for concentrate, tailings and paste backfill (Figure 4-13 and Figure 4-14). The bullet points below provide a summary of model results related to water demand and ore processing:

- Ore moisture is a source of water to the mill. At maximum rate of ore processing (*i.e.,* 2025-2029), ore moisture flow is slightly greater than 6 m^3/hr (Figure 4-13, upper panel).
- Concentrate water demand is shown in Figure 4-13 (lower panel). At maximum rate of ore processing, concentrate water demand is estimated to be on the order of 0.8 m^3/hr.
- Water requirements associated with tailings and paste backfill are shown in Figure 4-14. For the period 2022-2029, maximum demand for water to produce tailings is 90 m^3/hr for Base Case (*i.e*., tailings solids, 60% by weight; Table 3-5), whereas estimated demand for paste backfill is generally lower each year (*i.e.*, 40-55 m3/hr typically) although demand is estimated to be 85 m^3/hr in 2029, the last year of operations for the 4950 tpd scenario.
    - When aggregated, for any month over LOM, combined demand for water to produce tailings and paste is ≤140 m^3/hr under the Base Case.

Within the CWP-WTP-mill water balance, water supplies are managed to the FWT, which is a critical input of freshwater to the mill. At daily timestep, water cycles through the mill circuit, and any surpluses/deficits of water on account of ore moisture, concentrate, tailings and paste backfill activities, are accounted. Similar to discussion for the CWP (Section 4.4.3) and the FWT (Section 4.4.66), a key finding for Base Case is that demand for water at the mill is met by the available supply for the period 2022-2029. This is demonstrated by the time series data presented in Figure 4-15, which provides an accounting of 'water required' and 'water available' for concentrate, tailings and paste production. In Figure 4-15, time series showing water requirement and availability overprint one another, providing confirmation that mill water demands are met for the Base Case scenario.

Figure 4-13: Time series illustrating water available as ore moisture and water requirements associated with production of concentrate (2017-2029).

Figure 4-14: Water requirements associated with tailings and paste backfill over LOM (2017-2029).

Figure 4-15: Time series plots summarizing water requirements and availability in the mill for concentrate, tailings and paste production for LOM (2017-2029).

4.2.8 Sewage Treatment Plant

A time series shows measured and modelled discharges from the STP (Figure 4-16). Apparent in the plot are the increasing and variable rates of STP discharge which characterize the exploration and construction stages of site activity. For example, rates of discharge ranged from 10-40 m^3/day from autumn 2014 through to the end of 2015 but were much higher later in 2016 and throughout 2017, at the peak of construction (*i.e.*, 80-140 m^3/day).

Also apparent in Figure 4-16 are the modelled STP flows for the operations phase, which range from 65-85 m^3/day through to end of 2021, but are higher for the 2022-2029 period (*i.e.,* range from 70-100 m^3/day; average 90 m^3/day. For the period of future mining, the average flow rate is the equivalent of 3.75 m^3/hr, and thus, STP effluent discharge is a relatively minor flow in the overall site-wide water balance.

Figure 4-16: Time series showing modelled STP discharges at the Brucejack Mine for LOM.

4.2.9 WRTSF

Owing to placement of waste rock and tailings solids in the WRTSF, the volume of stored water within the facility will decrease over LOM. Measured and modelled changes in WRTSF volume are shown in Figure 4-17. Detailed bathymetric surveys were completed at the WRTSF in 2015, 2019, 2020, 2021 and 2022.

Measured and modelled data for the WRTSF indicate the following: the rate of change in WRTSF volume is generally constant over the construction and operations phases; stored

volumes are predicted to decrease from pre-mine levels of roughly 30 Mm^3 to 20.7 Mm^3; and the estimated change in volume (approximately 9.3 Mm^3) and duration of change (roughly 15 years; from 2015-2029) translate to an average flow rate (or displacement rate) from the WRTSF of 20.2 L/s. Further, a comparison of measured and modelled WRTSF volumes through 2022 provides an initial indication that this component of the model is reasonably well calibrated and producing reliable results.

Figure 4-17: Estimated change in WRTSF volume on account of waste rock and tailings placement within the facility.

4.2.10 Receiving Stream Stations

Modelled discharge records (2017-2031) are shown for receiving stream nodes BJ 3.10, BJ 2.62 and BJ 1.74 in Figure 4-18. Noteworthy observations based on assessment of these model results include:

- The data show a progressive increase in flow from BJ 3.10 to BJ 2.62 and BJ 1.74. The drainage area reporting to these three WBM nodes increases progressively, and so the result is expected.
- With respect to winter baseflows, flow rates at BJ 3.10 are on the order of 60-100 L/s. By comparison, flow rates at BJ 2.62 and BJ 1.74 are larger in magnitude on account of increased basin area.

Figure 4-18: Time series showing modelled daily discharges at BJ 3.10, BJ 2.62 and BJ 1.74 for LOM with no y-axis scaling (upper panel) and log y-axis scaling (lower panel). In the lower panel, the progressive increase in winter baseflow resulting from waste rock, tailings and effluent disposal in the WRTSF, is shown by the dashed red line.

- Following freshet and through the open-water period, discharges at the three receiving stream stations are much higher. For example, streamflow conditions at BJ 3.10 typically range from 0.1-1.0 m^3/s between May and November, while noted that higher rates of discharge (on the order of 2.0 m^3/s) may be sustained for short periods of time (days, weeks) during the ice-free period. Further afield at BJ 2.62 and BJ 1.74, discharge patterns and variability are similar, but the magnitude of flows are higher on account of larger catchment areas.

- Data in Figure 4-18 (lower panel) shows an increase in winter baseflow condition owing to mine development. As outlined above in Section 4.2.9, the placement of waste rock and tailings solids in the WRTSF results in water displacement and a reduction in volume of the facility. However, in parallel, diversions of water from BJ 3.10 weir (reclaim) and the ongoing return of treated effluent and contact water to the WRTSF, continue during LOM, which masks the water displacement signal to a degree.
- Receiver stream flow conditions are also summarized in Figure 4-1 and Figure 4-2 (in m^3/hr), with model results expressed as annual average values for operations (2022-2029) and closure/post-closure (2030-2050).

4.2.11 Water Balance Model Sensitivities

This section of the report discusses results for various sensitivities tested with the Brucejack WBM, including a tailings solid sensitivity, variable climate sensitivities, and a groundwater recharge sensitivity.

4.2.11.1 Tailings Solids, Operational Variability

The Base Case configuration of the WBM assumes the solids content of tailings and paste backfill is 60% by weight for the 2020-2029 period. Under this scenario, model results indicate the maximum water demand for tailings and paste backfill is roughly 140 m^3/hr for 4950 tpd milling (Figure 4-14). However, the solids content of tailings, in particular, may be subject to operational variability, therefore, this sensitivity aims to: demonstrate water requirements for tailings produced at varying solids percentages; and, illustrate the benefit of targeting 60% solids content for tailings rather than a lower target which requires input of additional water.

Results from the WBM confirm that as the percent solids of the tailings change (*e.g.*, from 60% solids to 55% or 50% solids), mill water demand increases accordingly (Figure 4-19). For example, the WBM sensitivity illustrates that mill demand can be expected to increase by 20 m^3/hr (*i.e.*, from 90 m^3/hr to 110 m^3/hr) as percent solids of tailings decrease from 60% to 55%. In contrast, mill water demand can be expected to increase by 45 m^3/hr should percent solids of tailings decrease from 60% to 50%.

In the winter when rates of groundwater recharge and surface runoff are at their annual minimums, mill operations are in part sustained by reclaim diversions from the BJ 3.10 weir, which are currently fixed at 70 m^3/hr for the mine site, as well as from stored water volumes in the CWP. Through this lens, the benefits of maintaining a tailings solids target of 60% becomes apparent, which in effect minimizes pressure on available water stores in the CWP storage and reduces mill water losses to the WRTSF as tailings are produced and disposed of during LOM.

Figure 4-19: Percent solids sensitivity analysis for tailings water requirements, Brucejack WBM – 4950 tpd case.

4.2.11.2 Groundwater Recharge Sensitivity

The Base Case configuration of the WBM incorporates expected case predictions of groundwater inflow to the underground mine. Under this scenario, model results show a progressive increase in recharge to the underground over the Project timeline. Furthermore, rates of inflow are anticipated to vary seasonally, with recharge to the mine being greater during the ice-free period compared to winter months (Figure 4-20 and Figure 2-10). Base Case results from the WBM also confirm demand at the mill may be met for the 4950 tpd scenario using existing water infrastructure and water management strategies.

Given the magnitude (*i.e.*, monthly fluxes on the order of 75-200 m^3/hr for the period 2022-2029) and importance of groundwater recharge as a source of water to the mill, a sensitivity was conducted to assess WBM changes under Lower and Upper groundwater recharge scenarios (Figure 4-20, upper panel). The technical specifics and modelling assumptions underpinning the Lower- and Upper-Case groundwater recharge scenarios are presented in Lorax (2023a). Key findings of this water balance sensitivity are summarized in the bullet points below:

- Total pumping from below ground to surface is not surprisingly greater for the Upper Case groundwater recharge scenario compared to the Lower Case groundwater scenario (Figure 4-20, upper panel).
  - In year 2023 for example, pumping to surface ranges from 70-125 m^3/hr for the Lower Case compared to 85-155 m^3/hr for the Upper Case.
  - By comparison, pumping to surface ranges from 100-160 m^3/hr for the Lower Case compared to 125-200 m^3/hr for the Upper Groundwater Case, by 2028 and 2029.
- Plots illustrating the management of water volumes at the TWT are shown in Figure 4-21 and Figure 4-22. In each of these figures, the upper panel shows raw model results from the WBM at daily timestep, whereas the lower panel shows 30-day average trendlines fitted to the raw model results, for ease of interpretation.
  - Regarding the release of treated effluent, WBM results predict proportionally more discharge to the WRTSF will occur for the Upper Case compared to Lower Case.
    - As a general strategy, treated effluent is 'bled' from the mill water balance when supply exceeds demand and the CWP volume is at capacity.
      - For example, by 2029 the WBM predicts releases of treated effluent to the WRTSF will vary from 25-313 m^3/hr over the course of the year for the Upper Case groundwater scenario, whereas releases to the WRTSF for the Lower Case are 25-287 m^3/hr (Figure 4-21, lower panel).
    - Owing to the long-term expected increase in groundwater recharge to the underground mine over LOM, it is noted that releases of treated effluent to the WRTSF increase with time accordingly, for all scenarios assessed (*i.e.,* Base Case, Lower Case and Upper Case).
  - In contrast, proportionally more water is managed from the TWT to the CWP under the Lower Case versus the Upper Case (Figure 4-22).
    - As outlined in previous discussion, water management infrastructure in the form of tanks, pumps and pipelines are in place at site, which allows for recycling of treated effluent to the CWP when there is available storage in the facility.
    - For the Lower Case, there is less water available to support mill activities than under Upper Case. Accordingly, rates of discharge of treated effluent to the WRTSF are lower (Figure 4-21, lower panel) and rates of recycle to the CWP are higher (*e.g.*, range typically between 25-60 m^3/hr in winter for 2028; Figure 4-22 lower panel) for Lower Case.

    - Note that over LOM the peak and total volumes of water recycled to the CWP decreases for Base Case, Upper Caser and Lower Case. This is because groundwater recharge increases with below ground development (Figure 4-20) and the requirement to recycle water to the CWP, in concept, lessens over this progression.

- Regarding reclaim diversions from the BJ 3.10 weir for the two groundwater cases, diversion rates while similar, are proportionally greater for the Lower Case than for the Upper Case (Figure 4-23 upper and lower panels).
    - In essence, any potential short comings in water supply for the Lower Case are compensated for by enhanced rates of reclaim diversion.
    - Note that modelled reclaim diversions for all cases and all time periods remain below the allowable threshold of 70 m^3/hr.
- Overall, the groundwater sensitivity analysis illustrates water demands at the mill may be met using existing infrastructures (*i.e.,* reclaim weir, the CWP, the WTP and TWT) and already developed water management strategies.
    - A key aspect of mine water management at the site is the ongoing balancing of flows/water volumes at the mill achieved by: reclaim diversions from Brucejack Creek; the release of treated effluent to the WRTSF when necessary; and, the recycling of excess water to the CWP when available storage in the facility exists.

Figure 4-20: Time series plots illustrating Base Case (grey), Lower Case (blue) and Upper Case (orange) model results for groundwater recharge to the UG mine (upper panel) and total pumping from below ground to surface (lower panel)

Figure 4-21: Time series plots illustrating Base Case (grey), Lower Case (blue) and Upper Case (orange) model results for release of treated water to the WRTSF. Raw results from the WBM are shown in the upper panel whereas results in the lower panel show a 30-day moving average.

Figure 4-22: Time series plots illustrating Base Case (grey), Lower Case (blue) and Upper Case (orange) model results for the recycling of treated effluent from the TWT to the CWP. Raw results from the WBM are shown in the upper panel whereas results in the lower panel show a 30-day moving average.

Figure 4-23: Time series plots illustrating Base Case (grey), Lower Case (blue) and Upper Case (orange) model results for the diversion of reclaim water from the BJ 3.10 weir. Raw results from the WBM are shown in the upper panel whereas results in the lower panel show a 30-day moving average.

Figure 4-24: Plot illustrating tailings water requirements for the 4950 tpd case (yellow line) compared to available water modelled for Base Case, the Lower Caw and Upper Case groundwater sensitivities.

4.2.11.3 Variable Climate Sensitivity

When the WBM is run in variable climate mode, a range of hydro-climatic output is computed for model nodes at daily timestep (Figure 4-25). Variable climate case (VCC) results are presented in this section to demonstrate the multi- realization capabilities of the WBM, as well, to discuss climate sensitive components of the WBM for the operations period.

WBM elements that are directly influenced by air temperature and precipitation inputs are as follows:

- natural catchment runoff reporting to the WRTSF and BJ 3.10 nodes (Figure 4-25, upper panel),
- the exchange of precipitation and evaporation at the WRTSF surface,
- runoff from the WR platform and km 72 NPAG quarry,
- background runoff reporting to Brucejack Creek at BJ 2.62 and BJ 1.74 nodes, and
- runoff that reports to the CWP via the contact water collection system (CWCS).

Figure 4-25: Examples of variable climate case output from the WBM for BJ 3.10 (upper panel, in m^3/s) and the CWCS (lower panel, in m^3/hr). Statistical outputs presented in the two charts are computed at daily timestep from 30-realizations of WBM output. For the simulation shown, measured climate inputs are read into the model for the pre-2022 time period versus the read-in of variable climate inputs thereafter.

Of the water fluxes identified above, the WBM term with a direct connection to either the supply/demand of water at the mill/WTP, is runoff from the CWCS (Figure 4-25, lower panel). Runoff from the CWCS is conveyed to the CWP, then directed to the WTP as required, with treated effluent managed in multiple ways: for example, treated effluent may be directed to the FWT to support mill/underground operations; or managed to the TWT whereby effluent may be released to the WRTSF or can be recycled back to the CWP when there is space in the pond.

During freshet, multi-realization output from the model predicts peak daily discharges on the order of 50-80 m^3/hr for dry years at the CWCS, compared to peak daily fluxes ranging from 100-190 m^3/hr for wet years. Inspection of wet vs dry realization results from the variable climate case model confirm that during wetter than normal years/conditions, more treated effluent is discharged to the WRTSF than during dry than normal years (Figure 4-26, upper panel). Further, the model confirms that during dry years/periods, recycling rates of effluent to the CWP are greater, compared to wet periods (Figure 4-26, upper panel). Figure 4-26, lower panel, shows modelled CWP volumes for the variable climate simulation for the 2022-2029 period.

Despite the differences in flow/volume reporting through the CWCS and CWP under variable climate, volumes at the CWP are predicted to remain relatively balanced through the winter (40,000 m^3) and open water periods (~15,000 m^3), a result suggesting mine site infrastructure such as the CWP, WTP and TWT are capable of maintaining a similar supply of water for mine site activities, whether climate conditions are wet, dry or typical.

Regarding required and available water for the production of concentrate, paste and tailings under variable climate, a key result from the variable climate case model is shown in Figure 4-27. This figure shows variable case climate results for paste water requirements (red line) versus paste water availability (blue line). Statistics in the plot (*i.e.*, min, mean and max) are computed at daily timestep from 30-realizations of WBM output for the variable climate case. The overprinting of the lines on the paste water plot is interpreted to mean water demand at the mill is met by the available water supply. Though not shown, the WBM returned similar results for concentrate and tailings water requirements for the variable climate simulation.

Figure 4-26: Variable case climate results showing release of treated effluent to the WRTSF (upper panel), recycling of water from the TWT to the CWP (middle panel), and CWP volume, for the 2022-2029 period. Statistical outputs presented in the three charts are computed at daily timestep from 30-realizations of WBM output.

Figure 4-27: Variable case climate results showing statistical outputs (min – upper panel; mean – middle panel; max – lower panel) for paste water requirements (red line) versus paste water availability (blue line). Statistics are computed at daily timestep from 30-realizations of WBM output for the variable climate case. The overprinting of the lines on the plot is interpreted to indicate that water demand at the mill is met by the available supply.

4.2.11.4 Variable Climate plus Climate Change Sensitivity

The variable climate mode of the WBM can also be executed to represent forward looking scenarios that consider climate change (refer to Section 2.3.4). Regarding air temperature and precipitation adjustments extending out to 2100, annual scalars are read into the WBM based on the RCP6.0 scenario developed from datasets prepared by the Scenario Network for Alaskan and Arctic Planning (SNAP). For the operations period sensitivity presented below, the site-wide WBM was initialized consistent with the setup for the variable climate case, with the exception that air temperature and precipitation trends for RCP6.0 were turned on for this sensitivity.

Over the period of operations (2022-2029), any changes in air temperature (0.5°C increase) and precipitation (+3% increase) attributable to climate change are anticipated to be very minor (Figure 2-6). Therefore, comparison of multi-realization output from the VCC versus VCC plus climate change models are expected to be very similar. By means of example, percentile plots comparing CWCS runoff volumes for the VCC versus VCC plus climate change scenarios are shown in Figure 4-28. Similarly, patterns of water management at the TWT (*i.e.,* flows managed to either the CWP or WRTSF) are evidently the same for the VCC versus VCC plus climate change scenarios (Figure 4-29, discharge of treated effluent to WRTSF plot shown).

Figure 4-28: Hydrographs for CWCS flow reporting to the CWP. Plots show output statistics (*i.e.*, 5th percentile – upper panel; 50th percentile – middle panel; 95th percentile – lower panel) based on 30 realizations of WBM output for the VCC versus VCC plus CC cases.

Figure 4-29: Discharge plots showing effluent release from the TWT to the WRTSF (*i.e.*, 5th percentile – upper panel; 50th percentile – middle panel; 95th percentile – lower panel) based on 30 realizations of WBM output. The plots compare model results for the VCC versus VCC plus CC cases.

4.3 Closure and Post-Closure Results

4.3.1 Overview

A water balance summary is provided for Brucejack Mine for the closure and post-closure phase (Figure 4-2). As for Operations, the WBM fully accounts for any background/non-contact runoff generated within the BJ 3.10, BJ 2.62 and BJ 1.74 watersheds. However, the model assumes the mine site, including the mill, access roads and related laydowns/pads, are reclaimed, with any runoff from these footprints assumed to report passively to either the WRTSF or Brucejack Creek below the BJ 3.10 weir. Following Active Closure and during Post-Closure, the STP and WTP are also assumed to be decommissioned, and therefore, are not shown in Figure 4-2.

Seepage flow from the underground mine to Brucejack Creek is depicted on Figure 4-2. Contact water fluxes generated from the flooded mine are simulated to average 14.9 L/s annually (or 54 m^3/hr). This is roughly 5 L/s higher than what was predicted by the 3,800 tpd model and is attributed to expansion of the mine extents as listed in the third bullet. Approximately 95% of contact water reports to Brucjack Creek above BJ-2.62, of which approximately 10% reports to the WRTSF. A further 4% of contact water reports to Brucejack Creek between BJ-2.62 and BJ-1.74. About 1% of contact water reports below BJ-1.74.

4.3.2 Fill Scenarios and Sensitivity, Underground Mine

To support closure costing and water quality predictive studies under the 2020 Mine Plan Update, two fill scenarios were considered for the Underground Mine. These scenarios were updated for the 4950 tpd Joint Application. The scenarios include Passive Fill and Accelerated Fill, noting the Accelerated Fill scenario is carried forward as a Base Case for water quality predictions (Lorax, 2023a).

For each scenario, it was assumed the underground mine would remain ‘open’ through the end of 2029, to support final phases of ore processing and allow any relevant remediation works to be carried out. Accordingly, filling under each scenario is assumed to begin on January 1, 2030. The bullet points below along with Figure 4-30, Figure 4-31, Figure 4-32 and Figure 4-33 summarize key findings of the modelling exercise.

Passive Fill

- Simulation work indicates passive filling of the mine will take place over a period of approximately 20 months (Figure 4-30, upper panel). Assuming flooding begins in January 2030, the underground mine floods and begins to fully discharge to

Brucejack Creek with timing coincident with the transition to autumn 2031 (Figure 4-31).

- Once filled, the mine pool will have an estimated volume of 1.54 Mm^3, with average elevation of the mine pool being 1,401 m asl (ranges seasonally from 1,393-1,407 m asl.
- Following filling, the GW model estimates seepage will discharge from the mine and report to Brucejack Creek upstream of BJ 2.62. Estimated travel times for seepage (*i.e.*, the time between mine pool filling and the 'daylighting' of contact water in the receiving environment) are on the order of days to weeks.
- The expected case estimate of seepage flow from the mine is approximately 15 L/s on average, with rates of seepage predicted to vary between 10-23 L/s over the year (Figure 4-31, lower panel; Figure 4-32, upper panel). For context, streamflow measurements at BJ 2.62 are estimated to be on the order of 55-135 L/s during winter months (Dec-Apr), with flows being much higher during the ice-free period (May-Nov) (Figure 4-32, lower panel).

Accelerated Fill

- The Accelerated Fill scenario explores time to fill following diversion of winter and freshet flows to the underground. Beginning in January 2030, diversion from BJ 3.10 is proposed from the BJ 3.10 weir at a rate of 70 m^3/hr for a 4-month period (Figure 4-30, lower panel).
- In May 2030 and for up to a four-month period, the Accelerated Fill scenario proposes the diversion of 20% MMD (mean monthly discharge) from the BJ 3.10 weir to the underground mine. By end of June or early July 2030, the combined volume from reclaim diversion, freshet diversion and GW inflow to the mine, fills the mine void, after which, no further diversion is proposed under this scenario (Figure 4-30, lower panel; Figure 4-31, upper panel).
    - Streamflow conditions at BJ 3.10 for the Passive Fill and Accelerated Fill scenarios for 2030 are compared in Figure 4-33 to illustrate the magnitude and duration of streamflow regime changes associated with the Accelerated Fill scenario.
- Assuming a maximum rate of treatment of 10,000 m^3/day, re-circulation to the WTP over a 15-month period (Figure 4-30, lower panel) enables treatment of approximately 4.5 Mm^3 of water, which is a volume 2.9-times greater than the mine void.

- Following filling of the mine void, the expected case estimate of seepage flow from the mine is 15 L/s on average, with rates of seepage predicted to vary between 8-22 L/s over the year (Figure 4-31, lower panel; Figure 4-32, lower panel). Owing to faster fill of the underground mine for the Accelerated Fill Scenario, groundwater seepage is expected to report to the receiving environment during summer of 2030 (Figure 4-31, lower panel; Figure 4-32, lower panel).
- The Accelerated Fill Scenario has been encoded in the WBM as Base Case to support robust water quality predictions for closure and post-closure phases.

Figure 4-30: Comparison of inflows to the underground mine for Passive Fill (upper) and Accelerated Fill (lower) scenarios. Under the Accelerated Fill scenario, water from the mine pool will be continually recirculated to the WTP for a 15-month period.

Figure 4-31: Comparison of mine pool volume predictions (upper) and GW seepage rates from the underground mine (lower) for the Passive Fill and Accelerated Fill scenarios.

Figure 4-32: Comparison of streamflow conditions at BJ 3.10, BJ 2.62 and BJ 1.74 for the Passive Fill (upper) and Accelerated Fill (lower) scenarios. GW seepage predictions (labelled Portal Discharge in the figures) for the two scenarios are also shown in the plots.

Figure 4-33: Comparison of streamflow conditions at BJ 3.10 for the Passive Fill and Accelerated Fill scenarios for 2030. The upper and lower panel show results without and with log-scaling on the Y-axis.

5. Summary and Conclusions

5.1 Review of Study Objectives

The objectives of the study are outlined in Section 1.3. Using the 2020 WBM as a basis (Lorax, 2020), Objective 1 is to develop a revised WBM that supports an updated water quality model (WQM) as required for the 2023 4950 tpd permit application. Note the revised WQM is described in full under separate cover (Lorax, 2023b). Objective 2 is to review and present the data used to support development of the revised site-wide WBM, including inputs from an updated mine plan, relevant monitoring studies, design/engineering studies, and operational water monitoring datasets. Key information is presented in Section 2 and Section 3 of this report.

Objective 3 of the study is to describe the WBM architecture and outline all relevant inputs and assumptions within the model. Material presented in Section 3, including GoldSim wire diagrams and representative model outputs, address this study objective. Objective 4 aims to discuss the calibration approach and present calibration results for the WBM. This objective is also addressed in Section 3, where outputs are presented to demonstrate model performance at both the watershed-scale (*i.e.*, BJ 3.10, Brucejack Creek below the WRTSF), as well as at the spatial extent of the mine site (*i.e.*, WTP and mill complex).

Objective 5 is to present and synthesize the results from the GoldSim WBM model. Section 4 of the report is dedicated to the presentation of the study results. As part of this exercise, results are presented for operations (2022-2029) and closure/post-closure (2030-2050 time periods. And finally, Objective 6 and the aim of Section 5 of the report is to summarize study results, discuss model sensitivities, identify data gaps and outline recommendations for future modelling studies.

5.2 Summary of Revised Model

A revised WBM has been developed for the Brucejack Mine. The model runs on a daily time step and is constructed using GoldSim software, which is the same platform used by the WQM. The WBM incorporates monthly mine plan data and schedules for ore processing, and accounts for placement of tailings in the underground mine as paste backfill and the placement of tailings and waste rock in the WRTSF.

The WBM is driven by a daily climate record of air temperature and precipitation measurements. Results are presented in Section 4 for a Base Case which uses measured climate data for 2015-2021 and daily average climate conditions thereafter. However, the model can read climate data inputs in other ways, including read-in of daily varying climate data and incorporation of climate change scenario data. The generation of runoff from

background catchments and select mine site footprints is computed within the model using daily climate data and a three-reservoir (*i.e.*, event flow, interflow, baseflow) watershed model, which has been calibrated to the instrumental record for hydrometric stations located within the Brucejack Creek watershed.

The model has been populated with measured data for the pre-2022 time period. This includes for example, climate data from the VOK climate station, streamflow data from baseline monitoring stations, measured data for the underground mine (*e.g.*, water use data, GW inflow data, sump pumping records), WRTSF bathymetry data and measured records of waste rock and tailings (volumes, tonnages) for materials already placed in the WRTSF. This means that for a calibration period of 2015-2021, results from simulations can readily be compared to measured water balance data. To the extent possible, the WBM is calibrated, or results are compared directly to, operational water monitoring datasets and previous studies.

5.3 Key Findings

5.3.1 Operations (2022-2029)

A generalized schematic of the site-wide water balance is presented in Figure 4-1, which summarizes annual average results (in m^3/hr) for a Base Case. Ore processing assumptions for the Base Case are presented in Table 3-5. At daily time step, the Base Case was computed using measured climate data for 2015-2021 and averaged daily climate inputs for 2022 onward. As a complement to Figure 4-1, text and figures presented throughout Section 4.4 provide the reader with a fulsome breakdown of WBM results.

For the Base Case, model results suggest a robust water supply is maintained at the mill with the existing water management system and allowable WRTSF reclaim volumes. The supply is maintained by underground dewatering flows, a combination of runoff from the CWCS and stored volumes within the CWP, recycling of water within the mill and diversion of water from the BJ 3.10 weir up to permitted allowances. Supply provided from reclaim is essentially fixed with the maximum allowable diversion being a cap at 70 m^3/hr, which is approximately 50,000 m^3/month. Supply in the form of contact water, captured by the CWCS, shows strong seasonal variability. Contact water volumes report through the collection system mainly following snowmelt and large rainfall events, noting that supply is not reliable from the CWCS in cold months. Supply provided by pumping from the underground mine is also seasonally variable, with winter again being the period when volumes are at a minimum, on an annual basis.

To meet demand at the mill through the winter, a general strategy adopted since operations began has been to operate the CWP at high stage/volume, which requires a fill period that

is scheduled in late autumn. Stored volumes within the CWP can then be sent to the mill (via the WTP and FWT), which complements the available supply, and prevents water deficit and upset from occurring within the processing circuit. WBM results can be audited for Base Case, or separate sensitivities *(e.g.*, groundwater recharge, variable climate), for indication of water deficit or depletion. For the Base Case, key indicators of the water balance including the CWP, FWT and mill Circuit showed stable and expected conditions which is evidence that water supply exceeded demand for the LOM simulation.

It is important to note that model predictions for GW inflow (to the underground mine) show an increasing trend with time, as the mine is built out to full extent. Annual minima in GW inflow are predicted to increase over LOM, which in concept, reduces water supply 'pressure' as the development timeline progresses. It will be important to periodically review GW inflow measurements and cross-compare these data to outputs from the GW model to ensure inflow rates are increasing over LOM, as predicted. It is also worth noting that the Base Case assumes the solids content of tailings and paste backfill is 60% by weight. The solids content of the tailings and paste backfill is subject to a degree of operational variability and results presented in Section 4 show mill water demands are sensitive to these operational parameters.

The WBM was configured using recent monitoring data. Measured data were relied upon extensively to describe, for example, seasonal staging of the CWP, modelled assumptions for reclaim diversions, pumping instructions from the CWP to the WTP, and the management of water at the TWT to either the CWP or the Brucejack WRTSF, within the WBM.

5.3.2 Closure and Post-Closure

A water balance summary is provided for the Brucejack Mine for the closure and post-closure phase (Figure 4-2, Figure 4-30, Figure 4-31, Figure 4-32, Figure 4-33). The model assumes the mine site, including the mill, access roads and related laydowns/pads, are reclaimed, with any runoff from these footprints assumed to report passively to either the WRTSF or Brucejack Creek below the BJ 3.10 weir. Under the closure and post-closure scenario, the STP and WTP are also assumed to be decommissioned.

With respect to flooding of the mine pool, the study reports on two filling scenarios: Passive Fill and Accelerated Fill. Simulation work indicates passive filling of the mine will take place over a period of approximately 20 months. Once filled, the mine pool will have an estimated volume of 1.54 Mm^3, with maximum elevation of the mine pool estimated to be 1,401 masl. Based on the associated WQM study (Lorax, 2023b), the Accelerated Fill scenario has been incorporated in the current closure plan presented in the Brucejack Mine

4950 tpd MA/EMA permit amendment application (Pretium, 2023) and includes recirculation of the mine pool (to the WTP) for a period of 15-months.

Following filling, contact water fluxes generated from the flooded mine are simulated to range seasonally between 10 L/s and 23 L/s, averaging 14.9 L/s annually (Figure 4-31). This is 5 L/s higher than what was predicted by the 3,800 tpd model and is attributed to expansion of the mine extents. Approximately 95% of contact water reports to Brucjack Creek above BJ-2.62, of which approximately 10% reports to the WRTSF. A further 4% of contact water reports to Brucejack Creek between BJ-2.62 and BJ-1.74. About 1% of contact water reports below BJ-1.74.

Appendix A: Brucejack Mine Water Balance Model - Development Sequence and Schedules

To represent past and future development sequences and schedules within the Goldsim WBM, the schedules presented in Table A.1-1, Table A.1-2, Table A.1-3, Table A.1-4 and Table A.1-5 are used for the 4950 tpd case. For the pre-2022 period, monthly actuals (*i.e.,* final reported values) are carried forward into the water model. In contrast, for the period 2022-2029, mine plan data presented in Pretium 2022 (*i.e*., 4950 tpd permit amendment) are used in the WBM.

LORAX ENVIRONMENTAL

Authorship

This update to the Brucejack Gold Mine Water Quality Model was prepared by Lorax Environmental Services Ltd. (Lorax) for Pretium Resources Inc. (Pretium). The report was written by Alison Shaw, Ph.D., P.Geo.; Patrick Mueller, B.Sc., P.Chem.; Robert Goldblatt, B.Sc., RPBio; John Dockrey, M.Sc., P.Geo.; and reviewed by Alison Shaw, Ph.D., P.Geo. Lorax Environmental Services Ltd. has relied on information available in scientific literature and information supplied by Pretium in preparing this report.

1 INTRODUCTION

2 MODELLING APPROACH AND ASSUMPTIONS
2.1 WATER QUALITY MODEL 2-1
2.1.1 OVERVIEW 2-1
2.1.2 GENERAL SITE-WIDE MITIGATIONS 2-2
2.1.3 MINE PLAN 2-3
2.1.4 GROUNDWATER MODEL 2-4
2.1.5 WATER BALANCE MODEL 2-5
2.1.6 MODELLING LOCATIONS AND PARAMETERS 2-10
2.1.7 WATER QUALITY MODELLING CASES 2-12
2.1.8 MODELLED VERTICAL MIXING OF THE WRTSF 2-12
2.2 SUMMARY OF UPDATES TO THE WATER QUALITY MODEL 2-15

3 SOURCE TERMS
3.1 BACKGROUND WATER QUALITY 3-1
3.1.1 OVERVIEW 3-1
3.1.2 BACKGROUND SOURCE TERMS 3-2
3.2 NPAG QUARRY 3-4
3.2.1 OVERVIEW 3-4
3.2.2 NPAG QUARRY RUNOFF SOURCE TERM EVALUATION 3-4
3.3 MINE SITE 3-6
3.3.1 OVERVIEW 3-6
3.3.2 MINE SITE RUNOFF 3-6
3.3.3 SURFACE WASTE ROCK 3-8
3.3.3.1 INSTANTANEOUS LOADS 3-8
3.3.3.2 POST-DEPOSITIONAL LOADS 3-9
3.3.4 WEATHERED SURFACE MATERIAL 3-12
3.4 UNDERGROUND MINE 3-16
3.4.1 OVERVIEW 3-16
3.4.2 UNDERGROUND MINE WASTE ROCK 3-16
3.4.2.1 INSTANTANEOUS LOADS 3-18
3.4.2.2 POST-DEPOSITIONAL LOADS 3-24
3.4.2.3 SURFACE EXPOSURE LOADS 3-25
3.4.3 UNDERGROUND MINE WATER 3-27
3.4.3.1 BACKGROUND GROUNDWATER 3-27
3.4.3.2 UNSATURATED UNDERGROUND MINE SOURCE TERMS 3-30
3.4.3.3 SATURATED UNDERGROUND MINE SOURCE TERMS 3-39
3.4.3.4 UNDERGROUND MINE WATER SOURCE TERM EVALUATION 3-46
3.5 WATER TREATMENT PLANT 3-54
3.5.1 OVERVIEW 3-54
3.5.2 WTP INFLUENT, EFFLUENT AND TREATMENT LEVEL 3-57
3.6 MILL 3-58
3.6.1 OVERVIEW 3-58
3.6.2 WTP SLUDGE SLURRY WATER 3-59
3.6.3 RECLAIM WATER 3-60
3.6.4 ORE MOISTURE 3-60
3.6.5 TAILINGS AND WTP SLUDGE LOADS 3-60

3.6.5.1 INSTANTANEOUS TAILINGS LOADS TO MILL 3-60
3.6.5.2 DIFFUSIVE LOADS FROM TAILINGS AND WTP SLUDGE TO WRTSF 3-64
3.6.6 PASTE BACKFILL BLEED WATER 3-67
3.7 SEWAGE TREATMENT PLANT 3-67
3.7.1 OVERVIEW 3-67
3.7.2 STP EFFLUENT 3-68
3.8 NITROGEN SOURCE TERMS 3-69
3.8.1 OVERVIEW 3-69
3.8.2 DATA SOURCES 3-69
3.8.3 EXPLOSIVES USE 3-70
3.8.4 MINE SITE AND NPAG QUARRY 3-71
3.8.4.1 OVERVIEW 3-71
3.8.4.2 MINE SITE WASTE ROCK SURFACES 3-72
3.8.4.3 MINE SITE RUNOFF 3-72
3.8.4.4 NPAG QUARRY PIT AND ROAD FILL RUNOFF 3-73
3.8.5 UNDERGROUND MINE 3-74
3.8.5.1 OVERVIEW 3-74
3.8.5.2 BLASTED ROCK AND MINE WATER 3-74
3.8.5.3 MINE WALL SURFACES 3-76
3.8.5.4 WASTE ROCK SURFACES 3-76
3.8.6 MILL COMPONENTS 3-78
3.8.6.1 OVERVIEW 3-78
3.8.6.2 ORE SURFACES 3-78
3.8.6.3 TAILINGS AND PASTE BACKFILL LOADS 3-79
3.8.7 NITROGEN SPECIATION 3-80

4 RESULTS
4.1 OVERVIEW 4-1
4.2 IDENTIFICATION OF PARAMETERS OF POTENTIAL CONCERN 4-1
4.3 WATER QUALITY PREDICTIONS 4-4
4.3.1 AMMONIA 4-4
4.3.2 NITRITE 4-6
4.3.3 NITRATE 4-8
4.3.4 SULFATE 4-9
4.3.5 ALUMINUM 4-11
4.3.6 ARSENIC 4-12
4.3.7 COPPER 4-14
4.3.8 SELENIUM 4-15

5 AQUATIC EFFECTS ASSESSMENT
5.1 INTRODUCTION 5-1
5.2 METHODS FOR ASSESSING RISK TO AQUATIC LIFE 5-2

1 Introduction

This report presents water quality predictions for Brucejack Mine under an increased production rate scenario. Brucejack Mine is an underground mine operation which is owned and operated by Pretium Resources Inc. (Pretium), a member of the Newcrest Group of companies (Newcrest). The mine is located approximately 60 km NNW of Stewart, B.C and began construction in September 2015 with gold production commencing in July 2017. This report has been prepared on behalf of Pretium in support of an application to amend *Mines Act* (MA) Permit M-243 and *Environmental Management Act* (EMA) Effluent Permit 107835 (PE-107835) to allow for an increase to the mine's production rate from average 3800 tonnes per day (tpd) to 4950 tpd.

Brucejack Mine is an underground mine operation with related surface infrastructure including a mill, a water treatment plant (WTP), a contact water pond (CWP), a waste rock and tailings storage facility (WRTSF), and a sewage treatment plant (STP) (Figure 1-1). Based on the proposed increased production rate, the total mine operating life is estimated to be 12.5 years.

The water quality model predicts how mining activities at Brucejack Mine will influence water quality in the receiving environment through life of mine (LOM) and into the post-closure phase, considering Base Case and Upper Case geochemistry conditions. Water quality predictions are provided for two stations: 1) BJ 3.10, the mine's regulated WRTSF discharge location; and 2) BJ 2.62, a downstream monitoring location in Brucejack Creek which will receive underground mine loads via groundwater pathways once the mine has been flooded following closure (Figure 1-1).

This report describes revisions to Brucejack Mine's water quality model that were made subsequent to the 2015 *MA & EMA* Permits Application (Pretium 2015) and following additional model revisions made in support of subsequent permit amendment applications for increased nitrite and nitrate discharge limits (submitted November 2016), co-deposition of water treatment plant sludge with tailings (submitted January 2017), extension of the PAG waste rock exposure time criterion (submitted January 2017), approval of an updated Cr Management Plan (submitted February 2017), and increased ore production rate of 3800 tpd (submitted April 2018 and referred to as the 2018 model). The water quality model was reviewed and updated in 2020 (Lorax 2020a) as part of the 5 Year Mine Plan and Reclamation Program Update (Pretium, 2020c).

The revised water quality model incorporates changes to the mine plan schedules, updated source terms based on experimental and operational data collected since 2015, an updated groundwater model (Lorax, 2023a) and a revised water balance model (Lorax, 2023b).

The objectives of this report are to:

- Describe the water quality model and outline all relevant inputs and assumptions within the model (Section 2).
- Present the water quality model source terms (*i.e.*, inputs) and any revisions made based on new monitoring or experimental data sets (Section 3).
- Present water quality model results as compared to previous model results, and relevant water quality guidelines and discharge limits (Section 4).
- Present an aquatic effects assessment for model results that are higher than previously assessed (Section 5).
- Summarize the 4950 tpd water quality model results and the results of the associated effects assessment (Section 6).

2 Modelling Approach and Assumptions

This chapter describes the approach and assumptions for the Brucejack Mine water quality model. A detailed description of the water quality model is presented, followed by a summary of updates to the model as compared to the 2020 model (Lorax, 2020a).

2.1 Water Quality Model

2.1.1 Overview

The Brucejack Mine water quality model employs a mass balance approach that accounts for background water quality and runoff volumes reporting from undisturbed portions of the Brucejack Creek watershed, as well as chemical loads emanating from mine sources (*e.g.*, underground workings, waste rock, tailings discharge) and water management structures (*e.g.*, Contact Water Pond (CWP), the water treatment plant (WTP) and the sewage treatment plant (STP)). Loads associated with solids such as deposited waste rock, explosive-related nitrogen species and tailings, were pre-determined and input directly to the mass balance calculations. Each component of the existing environment and mine site area that may contribute to water quality at the outlet to the WRTSF (BJ 3.10) and at Brucejack Creek monitoring station BJ 2.62 has been included in the water quality model.

Background water quality signatures are derived from pre-construction monitoring (ERM Rescan, 2014), while mine-related water quality signatures are based on geochemical source terms as described in Section 3. The water quality model was constructed following the structure of the mine's water balance model (Lorax, 2023b) which incorporates the results of an updated groundwater model (Lorax, 2023a). The water balance model tracks all background and mine-impacted waters that report to the waste rock and tailings storage facility (WRTSF) and various monitoring sites along Brucejack Creek. An overview of the water balance is provided in Section 2.1.5, with additional information on derivation of the water balance provided in the water balance model update (Lorax, 2023b).

The water quality model assumes the WRTSF is vertically stratified for most of the year, but fully mixed during the month of October when the lake experiences temperature-driven turnover events. This assumption is supported by lake profiling data collected through monitoring programs developed for the WRTSF (described in Section 2.1.8).

As for the water balance model, the water quality model was developed in GoldSim; a flexible, object-oriented software tool that is designed for carrying out dynamic, probabilistic simulations of complex systems. GoldSim can be applied to deterministic simulations in which all inputs are pre-determined by the user. This approach was used to

predict water quality concentrations at mixing locations within the conceptual flow networks defined for each of the specified mine phases.

The model uses monthly time steps throughout the duration of mine life and includes the following:

- Construction phase: 21 months, from September 2015 through May 2017, which corresponds to the two-year construction phase;
- Operations phase: 151 months, from June 2017 to December 2029;
- Closure phase: 36 months, from January 2030 to December 2032, which corresponds to the estimated timing and duration of the closure phase; and
- Post-closure phase: 192 months, from January 2033 to December 2049, which corresponds to the first 16 years of the post-closure period.

Site data acquired through to the end of 2021 have been used to update the water quality model. The water quality model results presented in this report cover the operations, closure and post-closure phases from January 2022 through to the end of December 2049. Loadings associated with construction and mining activities prior to January 2022 have been incorporated into the model since a portion of these loads will impact water quality of the WRTSF (as determined by the residence time in the WRTSF, which is estimated to be approximately 18 months).

The model generally follows a mass balance approach and assumes that no mass is lost through geochemical reactions or natural biogeochemical processes. A notable exception is for underground mine water where secondary reactions are incorporated into the source terms for certain parameters, as described in Section 3.4.3. In the WRTSF, various natural biogeochemical mechanisms are expected to attenuate trace element and nutrient concentrations (*e.g.*, biological uptake of nitrogen and phosphorus, as well as metal scavenging by particles). Attenuation processes are not modelled, but the distribution of nitrogen among inorganic species (*i.e.,* ammonia, nitrite and nitrate) is adjusted to account for nitrification processes that occur naturally in WRTSF.

2.1.2 General Site-Wide Mitigations

Water quality predictions presented in this report assume implementation of several mitigation strategies. For the purpose of water quality modelling, it is assumed that the mitigations will be effective as intended. These mitigations include:

- A Sewage Treatment Plant (STP) which treats grey and blackwater from the mine site facilities to effluent quality discharge requirements throughout life of mine (LOM). Treated water is discharged to the WRTSF;

- Management of contact water, via collection ditches, pipelines and related structures, as per the OMS Manual - Water Management Plan (SRK, 2020);
- A Water Treatment Plant (WTP) which treats underground seepage and surface contact water from the site contact water collection system to effluent quality discharge requirements throughout LOM. Treated water is discharged to the WRSTF or is recycled in the mill and mine water supply;
- Management of potentially acid generating (PAG) waste rock through deposition of waste rock into the WRTSF. It is assumed that suspended sediments associated with the waste rock will continue to largely settle in the lake, which acts as a natural sedimentation pond. It is further assumed that any sediments remaining in suspension will be managed using the sediment control curtains;
- Deposition of thickened tailings solids and effluent to the bottom of the WRTSF via a suspended tailings pipeline; it is assumed that fines associated with tailings will continue to remain at the bottom of the lake, similar to natural fine grained sediment;
- Management of blasting-related nitrogen compounds following source control measures and best management practices as outlined in the Nitrogen Management Plan (NMP; Pretium 2022); and
- Management of hexavalent chromium associated with cement use in the underground mine as described in the Chromium Management Plan (CMP; Pretium 2019b).

2.1.3 Mine Plan

The Brucejack Mine water quality model and the associated groundwater and water balance models have been developed based on the 4950 tpd Joint Application mine plan provided to Lorax in September 2022. There are minimal changes in the mine development extents of the 4950 tpd mine plan (presented in Chapter 3 of the 4950 tpd Joint M-243/PE-107835 Amendments Application; Pretium, 2023) compared to those of the 3800 tpd mine plan presented in the 2020 Mine Plan and Reclamation Program Update (2020 Update) submission (Pretium, 2020c). However, because the ore production rate will be higher, the mine life will decrease (with the end of operations planned for 2029 rather than 2032).

The mine schedules used for development of water quality model source terms are presented within the associated source term sections. The model applies actual mine schedules through 2021 and projected schedules for 2022 through 2029.

2.1.4 Groundwater Model

The 4950 tpd groundwater model update is described in Lorax (2023a). The groundwater model provides the following predictions that are used to inform water balance and water quality models:

- Inflows to the underground mine during operations;
- Flooding rates into the underground mine void at closure;
- Time to flood the underground mine void and the ultimate flooded elevation in the mine at closure;
- The timing, volumetric flux and spatial distribution of contact water draining from the underground towards surface water receptors at closure; and,
- Changes in baseflow at surface water receptors during operations and closure.

The 4950 tpd groundwater model is an extension of the 2020 groundwater model prepared for the 2020 5 Year Mine Plan and Reclamation Program Update (Lorax 2020b). The 2020 groundwater model synthesized data collected in multiple field programs executed through the end of 2018. The 2020 model was calibrated to steady-state baseline and transient operations conditions. Baseline calibration targets included annual average water levels and baseflow in Brucejack Creek. The operations phase calibration targets included high resolution groundwater levels and monthly average underground dewatering rates collected between 2011 and 2018, the latter ~3.5 years corresponding to a period of active mining. The 2020 model achieved an acceptable calibration to both steady state and transient targets, capturing both seasonal fluctuations and long-term trends.

The 2020 groundwater model was updated with approximate as-built mine extents, provided by Pretium in annual snapshots, and recent climate data to simulate water levels and underground dewatering rates on a monthly basis for the 2019 to 2021 validation period. The model continued to reasonably simulate data trends over this period, and importantly, reasonably simulate water levels at 2018-series wells where data were previously unavailable. Acceptable model performance over the validation period precluded the need to recalibrate hydraulic parameters prior to implementing the 4950 tpd mine plan.

The 4950 tpd mine plan was provided by Pretium and included developments planned for the remaining life of mine (2022 through 2029). The 4950 tpd mine plan was implemented on a monthly time step to capture the seasonality of underground dewatering rates for future operations. Per the as-built operations simulations, stopes were simulated as actively dewatered for one month followed by waste rock or paste backfill the following month. All

developments were kept open for the duration of operations. The groundwater model assumed that dewatering would conclude at the end of mining in 2029.

The 4950 tpd groundwater model simulates the closure period in two phases. The closure simulations assume that underground developments will remain open with plugs installed at the West Zone and VOK portals. The developments were reconfigured to accurately represent the volume of mine void and were assigned a high hydraulic conductivity (*i.e.*, a low resistance to flow) to enable the development of a flat water table across the mine void at closure.

The first phase of closure simulations comprised a series of steady-state model runs to develop an inflow rate versus mine pool elevation curve. This was used in tandem with the mine volume elevation curve to compute mine reflooding time. These simulations also revealed the mine pool elevation at which contact water from the mine starts to reach Brucejack Creek and contact water volumetric flux.

The second phase of closure simulations represents long-term closure when the mine pool has reached its equilibrium elevation. This was simulated as a transient run lasting five years, progressed on a monthly time step. This simulation captures seasonality in both the underground flooded elevation and contact water fluxes to Brucejack Creek.

2.1.5 Water Balance Model

The water balance model for the Brucejack Mine has been updated based on a review of site operations and plans and is presented in Lorax 2023b. The water balance is a detailed interpretation of the mine and water management plans, with consideration of baseline and operational climate, hydrometric, and hydrogeological data collected for the mine site area (*i.e.*, the area that comprises all mine infrastructure within the Brucejack mining leases). The section below presents an overview of the water balance developed by Lorax which has been integrated into the water quality model described above.

The water balance for the Brucejack Mine was derived using information from the following sources:

- Site and regional climate data and local streamflow data (*i.e.*, BJ 3.10, BJ 1.74) spanning the baseline, construction, and operations phase;
- Drainage areas, glacier extents and runoff coefficients;
- Mine schedules for waste rock, ore and tailings consistent with annual reporting through to the end of 2021 and the 4950 tpd mine plan (presented in Chapter 3 of the 4950 tpd Joint M-243/PE-107835 Amendments Application; Pretium, 2023);
- Underground mine design and mill feed rates;

- Estimated groundwater inflows and seepage rates for the underground mine as presented by Lorax (2023b); and,
- Operational water monitoring datasets, including data describing the underground mine water use (drilling, dust suppression), process plant water use and freshwater make-up requirements, tailings density and properties.

The water quality model results presented in Section 4 use measured climate data inputs for the pre-2022 time period; whereas, simulated average daily climate values are applied for the subsequent time period. The simulated data were developed from a 30-yr portion of the PNWNAmet daily- gridded dataset, and continuously looped, for the duration of the simulation; PNWNAmet data spanning the period 1983-2012 are used to generate the average daily air temperature and precipitation inputs. Measured and synthetic climate data used in the modelling analysis are discussed further in Section 2.3 and Section 3.2 of (Lorax, 2023b).

The water balance configurations for the operations and post-closure phases used to develop the water quality model are illustrated in Figure 2-1 and Figure 2-2 respectively.

The following are the main water management components represented in the water balance model for the operations phase:

1. A contact water pond (CWP) which is assumed to receive approximately 60% of surface runoff from the mine site contact water collection system (primarily the mill and camp pads). This water is pumped to the WTP for treatment. The remaining 40% is assumed collection system leakage that reports directly to the WRTSF or Brucejack Creek below the WRTSF;
2. Dewatering from the underground mine, which includes groundwater inflows, paste backfill bleed water (*i.e.*, the excess water not consumed in the paste backfill cementation reaction) and water from the Freshwater Tank that is directed to the underground mine to support drilling/dust suppression activities, then captured in mine sumps;
3. The water treatment plant (WTP), which treats water from the CWP and the underground mine. The treated effluent is used in the mill process, with any excess not required for process discharged to the WRTSF, or re-cycled back to the CWP;
4. Discharge of effluent from a sewage treatment plant (STP) to the WRTSF;
5. A mill which discharges a tailings slurry to the WRTSF and pipes paste backfill to the underground mine;

6. The conveyance of contact flows from the NPAG Quarry and the waste rock platform to the WRTSF via surface runoff; and
7. Deposition of waste rock subaqueously in the WRTSF and to the underground mine as backfill.

The operations phase components of the Brucejack Mine are summarized in Figure 2-1, along with other water inflows and losses relevant to the WRTSF and receiving stream nodes (*i.e.*, BJ 3.10, BJ 2.62 and BJ 1.74). Over the course of a year, monthly average discharges from the WRTSF during operations are expected to range from 0.05 to >1.5 m^3/s. Outflow from the WRTSF includes runoff from background/contact sub-catchments reporting to the facility, as well as contributions of water displaced by the deposition of waste rock and tailings solids. Total lake water volume capacity at the start of operations is approximately 28.5 Mm^3 and is reduced to 21.0 Mm^3 at the end of operations.

At closure, mine facilities will be decommissioned, and the underground mine workings will be flooded, starting in January 2030. The natural flooding from groundwater inflows will be accelerated by pumping water from the WRTSF into the underground mine at a rate equal to 70 m^3/hr (~ 50,000 $m^3/month$) between January and April and then at an increased rate equivalent to 20% of the mean monthly flows at BJ 3.10 during May, June, and July. Underground mine water will be treated by the WTP at a rate of 10,000 m^3/day and recirculated back underground throughout the flooding time period as well as for an additional eight months to ensure that water quality is effectively managed.

The reconfiguration of flows and the associated water management plan during closure is reflected in the post-closure water balance illustrated in Figure 2-2. The post-closure water balance includes the following mine-related components:

- Flows from the NPAG Quarry;
- Flows from the reclaimed plant site; and
- Drainages from the underground mine which flow to the WRTSF and Brucejack Creek via groundwater pathways.

In addition to accounting for mine-related loads, the water quality model predictions incorporate contributions from Camp Creek and other non-contact runoff surrounding the mine site.

Figure 2-1: Brucejack Mine Water Balance Model schematic for the operations phase, 2022-2029 (from Lorax 2023b).

Figure 2-2: Brucejack Mine Water Balance Model schematic for the post-closure phase, 2030-2050 (from Lorax 2023b).

2.1.6 Modelling Locations and Parameters

Water quality predictions are generated for two locations:

- BJ 3.10, located at the outlet of the WRTSF (Figure 1-1); and
- BJ 2.62, a monitoring station in Brucejack Creek, located downstream of the WRTSF.

During the operations phase, mine-affected inputs are directed to the WRTSF. Monitoring station BJ 3.10 at the WRTSF outlet is the mine's final discharge compliance location where WRTSF discharge limits specified in PE-107835 apply.

During the post-closure phase, once the mine is flooded, the majority of groundwater flow paths from the underground mine discharge to the upper reaches of Brucejack Creek between the WRTSF outlet and BJ 2.62. Monitoring station BJ 2.62 is located at the bottom of a cascade downstream of the WRTSF and Camp Creek; the cascade is expected to result in fully-mixed conditions upstream of BJ 2.62. BJ 2.62, therefore, represents a key location for the post-closure water quality predictions.

Water quality predictions were generated for the parameters listed in Table 2-1, including major ions representative of mine-related inputs and all parameters with BC freshwater aquatic life (FWAL) guidelines. Neither pH nor TSS was modelled, as they depend on a wide range of factors that are not fully accounted for in the mass loading approach.

Table 2-1:
Water quality parameters included in the Brucejack Mine Water Quality Model

Parameter	Formula
Major Anions	
Ammonia (as N)	NH_3-N
Nitrate (as N)	NO_3-N
Nitrite (as N)	NO_2-N
Chloride	Cl^-
Fluoride	F^-
Sulfate	SO_4^{2-}
Phosphorus	P
Metals (Total and Dissolved)	
Aluminum	Al
Antimony	Sb
Arsenic	As
Barium	Ba
Beryllium	Be
Bismuth	Bi
Boron	B
Cadmium	Cd
Calcium	Ca
Chromium	Cr
Cobalt	Co
Copper	Cu
Iron	Fe
Lead	Pb
Lithium	Li
Magnesium	Mg
Manganese	Mn
Mercury	Hg
Molybdenum	Mo
Nickel	Ni
Phosphorous	P
Potassium	K
Selenium	Se
Silicon	Si
Silver	Ag
Sodium	Na
Strontium	Sr
Thallium	Tl
Tin	Sn
Titanium	Ti
Uranium	U
Vanadium	V
Zinc	Zn

2.1.7 Water Quality Modelling Cases

Water quality predictions through operations, closure and post-closure mine phases were generated for a Base Case and an Upper Case. The Base Case represents an expected condition, whereas the Upper Case applies upper case geochemical source terms to all mine-related inputs to the model. Both cases are based on average flow conditions for all flows. Additional model sensitivities were assessed in previous water quality models, as described below.

The 2015 *MA & EMA* Permits Application water quality model (Pretium, 2015) evaluated the sensitivity of the water quality model to elevated geochemical source terms, elevated background, elevated TSS inputs from Camp Creek, a permanently stratified lake system and elevated hydraulic conductivity in the surrounding bedrock. The water quality model results showed that the model was relatively insensitive to most of these variables, with the exception of the geochemical source terms.

The 2018 water quality model (Lorax, 2018) assessed the influence of upper case geochemical sources terms, in addition to two different waste rock and tailings management strategies. The first strategy evaluated considered a scenario where all waste rock is placed in the WRTSF (Scenario 1), whereas the second scenario maximized the amount of waste rock placed as backfill in the underground mine (Scenario 2). The water quality predictions for the two scenarios showed similar trends with most parameters showing only minor differences.

Based on an assessment of previous water quality model sensitivity results, the main area of model uncertainty identified was geochemistry. For this reason, Base Case and Upper Case geochemistry scenarios were carried forward for subsequent water quality models (the 2020 model (Lorax, 2020a) and the model presented herein).

2.1.8 Modelled Vertical Mixing of the WRTSF

Northern lakes are typically dimictic, meaning that the water column becomes fully mixed in the spring and fall due to seasonal changes in surface water temperature. As surface water warms after ice melt it reaches its maximum density at approximately 4 °C. At that temperature, surface water will be more dense than the rest of the water column and sink which causes the whole water column to become mixed. Warming of the surface layer in summer produces a stratified water column, with a warm surface layer on top of a colder bottom layer. In the fall, as the surface layer cools to 4 °C the water column undergoes another period of mixing before ice forms.

This dimictic behaviour is applied to the WRTSF, as observed from the 2019 timeseries of vertical profiles of temperature (Figure 2-3). The temperature profile in late June, after ice

melt, shows that the whole water column had become warmer as the warmer and denser surface water sank. By late July, the water column had become stratified, with warm water in the upper 8 m and 4-5°C through the rest of the water column. By late September, the water column had warmed to approximately 6°C as the water column mixed again before ice formed.

Figure 2-3: Vertical profiles of temperature in the WRTSF during spring and fall of 2019.

Beginning in 2020 the WRTSF no longer underwent a spring turnover. This is likely due to increasing concentrations of total dissolved solids (TDS) in the WRTSF over time, which increases the density of the water. This can be seen by comparing the specific conductance, a measure of TDS, of the deeper portion of the WRTSF in 2019 (~300 µS/cm) to 2020 (~350 µS/cm) (Figure 2-4). In the spring of 2020, when ice on the WRTSF melted and runoff from snowmelt drained to the WRTSF, this created a low-density (low TDS) freshwater lens on top of the higher density (high TDS) water column. While the surface layer density would have increased as it warmed from 0°C to 4°C, the effect of temperature on density was not enough to overcome the density difference between surface and deep water due to TDS; therefore, surface water did not sink to depth in spring. Vertical profiles

of temperature in July of 2019 and 2020 illustrate the differences in vertical mixing between these years (Figure 2-4). In 2019, spring turnover caused the deep water of the WRTSF to increase from 2°C in winter to 4°C in June (Figure 2-3) whereas in 2020, with no spring turnover, the sub-surface layer remained at 2°C in July (Figure 2-4).

Figure 2-4: Vertical profiles of temperature and specific conductance in the WRTSF during July of 2019 and 2020.

The freshwater lens on the WRTSF in the spring of 2020 mixed with deeper water throughout the summer, which increased the TDS of the surface layer. In the fall, the TDS difference between the surface layer and sub-surface layer was small, which allowed fall turnover to occur when the temperature of the surface layer decreased to 4°C. The same pattern of no turnover in the spring and a turnover occurring in the fall was observed in 2021. Thus, the increase in TDS of the WRTSF over time, caused by placement of waste rock and tailings in the WRTSF, has changed the water body from dimictic to monomictic, with only a fall turnover.

The water quality model, having monthly time steps, previously had the water column fully mixed in July and October and stratified during other months. The base case for the current model is to be fully mixed in October and stratified for all other months. When the water column is stratified the model has two layers. The upper layer is represented by the upper 10 m of the WRTSF and the lower layer extends from a depth of 10 m to the bottom of the WRTSF (~58 m depth). The upper 10 m of the WRTSF contains approximately 24% of the total WRTSF volume. Modelled loadings to the surface layer are from background

runoff, uncaptured mine site runoff, and NPAG Quarry runoff. Modelled loadings to the lower layer are from waste rock deposition, WTP discharge, STP discharge, and tailings disposal.

2.2 Summary of Updates to the Water Quality Model

The water quality model has been revised and updated to reflect current operations and plans for future development. The revisions from the last major modelling exercise (Lorax, 2020a) include updates to various source terms based on new data, the incorporation of new terms based on trends observed in the monitoring data sets, changes to the mine plan schedules, and revisions to water management plans.

The major revisions incorporated into the current water quality model include the following:

- An updated groundwater model which has been calibrated to observed flows (Lorax, 2023a).
- Revision to the site's water balance based on observed flows, changes to the mine plan and updated water management plans (described in Lorax, 2023b).
- Revision to assumptions regarding WRTSF mixing behaviour where a spring turnover event is not included in the model beyond 2019.
- Application of operational monitoring results to the background source term for parameters where recent data show lower concentrations than baseline data sets.
- Revision to the source terms applied for surface runoff at the mine site based on site monitoring data for CWP influent.
- Updates to the underground mine water source terms based on new kinetic tests, site monitoring data, and solubility constraints.
- Revision to the tailings source terms based on operational data collected at the Semi-Autogenous Grinding (SAG) mill.
- Refinement of water treatment plant removal efficiencies based on operational data sets.
- Revision to the STP effluent term using operational water quality data sets for all parameters.

3 Source Terms

The Brucejack Mine water quality model incorporates the combined effects of all major background (non-contact) and mine-related (contact) sources. The water quality predictions presented in Chapter 4 are based on source terms developed for the following components:

- Background sources;
- NPAG Quarry runoff;
- Mine site runoff;
- Waste rock and weathered material from surface excavations deposited in the WRTSF;
- Underground Mine waste rock placed in the WRTSF;
- Underground Mine water;
- Water Treatment Plant effluent and solid phase sludge;
- Tailings deposited in the WRTSF and placed in the underground mine as paste backfill;
- Sewage Treatment Plant effluent; and
- Blasting-related nitrogen compounds.

The derivation of source terms for each of these components is described in the following sections. In each case, the approach used to develop source terms is reviewed, along with the predicted parameter concentrations or loadings as compared to data acquired between 2015 and 2021. Source terms developed for the water quality model are based on static and kinetic geochemical data sets, experimental data, as well as operational data sets acquired through the various site monitoring programs.

3.1 Background Water Quality

3.1.1 Overview

Concentrations of non-contact water used in the water quality model were derived from monitoring datasets for BJ 3.10, at the outlet of the WRTSF. Baseline monitoring that occurred in 2011 through 2013 is the primary dataset used for non-contact water (ERM Rescan, 2014). This dataset reflects the cumulative influence of background precipitation, evaporation, groundwater, and surface runoff to the lake, and also accounts for waste rock

deposited in the WRTSF prior to 2013, and any other activity that may have impacted water quality, up to the completion of baseline monitoring in 2013. The baseline data set includes drainage from the Goldwedge Property that reports to the WRTSF via Catear Creek (also known as Tributary 2 (Figure 1-1)) including lakes along Catear Creek where Goldwedge tailings were placed. Water quality data from monitoring conducted by Newhawk between 1987 and 2001 (n = 56 samples) had high method detection limits and a limited number of parameters that were analyzed; therefore, these data were not used for source term development.

The baseline dataset was compared to BJ 3.10 monitoring results from 2017 through 2021 to identify parameters with concentrations that were overestimated by the baseline monitoring dataset. This could result from improved analytical detection limits, or from the larger number of samples in recent monitoring for certain seasons than was possible to collect during baseline monitoring. If the concentrations for a parameter were lower in recent monitoring than in baseline monitoring, then the recent monitoring results were used to derive non-contact water source terms for that parameter. If the concentrations from recent monitoring were higher than from baseline monitoring, then the baseline monitoring results were used to derive non-contact water source terms. Previous water quality models only used baseline monitoring results for deriving non-contact water source terms.

The flows assigned to the non-contact water source terms are based on the water balance model (Lorax, 2023a; described in Section 2.1.5). The background source terms derived from the BJ 3.10 datasets were used for all non-contact water.

3.1.2 Background Source Terms

The monitoring data were grouped into quarters (three-month long periods) to reflect distinctive seasonal hydrologic phases at the site. At the Brucejack Mine, site conditions are most consistent with three-month periods that are shifted one calendar month forward, relative to normal calendar quarters. The background source term values were therefore calculated by applying a “Shifted Quarters” approach using the following time intervals:

- Shifted Quarter 1: February, March, and April;
- Shifted Quarter 2: May, June, and July;
- Shifted Quarter 3: August, September, and October; and
- Shifted Quarter 4: November, December, and January.

Background water quality source terms were calculated from median values for each Shifted Quarter dataset (Table 3-1) and applied to both the Base Case and Upper Case models.

Table 3-1:
Background (Brucejack Lake and Upper Brucejack Creek) source terms for Base Case scenario

Parameter	Shifted Quarter 1 (Feb/Mar/Apr) (mg/L)		Shifted Quarter 2 (May/Jun/Jul) (mg/L)		Shifted Quarter 3 (Aug/Sep/Oct) (mg/L)		Shifted Quarter 4 (Nov/Dec/Jan) (mg/L)

3.2 NPAG Quarry

3.2.1 Overview

Since 2015, approximately 1.1 Mt of rock has been excavated from the NPAG Quarry to provide material for building foundations, roads and other construction activities at the mine site (Table 3-2). It is projected that approximately 50,000 t of NPAG Quarry rock will be excavated on an annual basis through operations. The NPAG Quarry is located near the southeast end of the WRTSF and runoff from the NPAG Quarry flows into the WRTSF. The NPAG Quarry is comprised predominantly of volcanic (plagioclase-hornblende) porphyry, with lesser amounts of conglomerate (S3), and negligible sulfide mineralization. Results from the preliminary ML/ARD characterization (Pretium, 2015) and subsequent confirmatory sampling programs (Pretium, 2016; 2017; 2018a; 2019a; 2020c; 2021; 2022a), as well as the 2020 Environmental Monitoring Review (Lorax, 2020d) confirm that rock excavated from the NPAG Quarry is consistently NPAG with low neutral metal leaching potential. Runoff source terms were developed to capture contributions from drainage in contact with exposures in the NPAG Quarry.

Table 3-2:
Annual NPAG Quarry excavation schedule

Year	NPAG Quarry Rock Blasted and Excavated (t)
2015	417,424
2016	450,026
2017	45,813
2018	84,718
2019	73,000
2020	5,000
2021	38,000

Note: that the projected excavation of NPAG Quarry rock is 50,000 t/year

3.2.2 NPAG Quarry Runoff Source Term Evaluation

Shake flask extraction (SFE) tests carried out on rock samples collected from the NPAG Quarry are used to predict the quality of surface drainages from the NPAG Quarry to the WRTSF. Median and 90th percentile values of the cumulative SFE results for 51 samples are used to represent Base Case and Upper Case source terms, respectively. The concentration values assigned to NPAG Quarry runoff flows, as designated by the site water balance, are presented in Table 3-3, as compared to BC FWAL guidelines which are provided for reference.

Table 3-3:
Source terms for NPAG Quarry runoff

Parameter	Units	BC FWAL		NPAG Quarry source terms based on SFE data (n=51)	
		Long-term	Short-term	*Base Case*	*Upper Case*

Zn	mg/L	0.0075	0.033	0.001	0.003

Notes: Base Case and Upper Case values are based on median and 90th percentile values for 51 SFE analyses; NP = none proposed; BC FWAL = water quality guidelines for the protection of freshwater aquatic life (ENV 2017, ENV 2019a); values in bold italics are higher than the long-term BC FWAL; values in bold are higher than the short-term BC FWAL.

3.3 Mine Site

3.3.1 Overview

A total of ~1.5 Mt of waste rock and 111 kt of weathered surface material were excavated from the mine site surface area to support the construction of site roads and pads for various facilities including the mill, Phase 2 Camp and CWP. Construction of the mine site was initiated in September 2015 and continued during 2016, with the majority of excavation occurring in Q1 and Q2 of 2016.

Geochemical source terms were developed for 1) mine site run-off associated with exposures from surface excavation; 2) mine site surface waste rock deposited in the WRTSF; and 3) weathered surface material placed in the WRTSF. For waste rock placed in the WRTSF, instantaneous and post-depositional loads were calculated. The instantaneous surface waste rock load represents the mass of available soluble constituents that are instantaneously released into solution. The post-depositional loads represent the longer-term loads released following deposition of the waste rock in the WRTSF. The approach for derivation of each of these water quality model inputs are described in the sections below.

3.3.2 Mine Site Runoff

Contact water associated with runoff from the core infrastructure portion of the mine site is collected by the contact water collection system, which directs water to the CWP (Figure 1-1). Non-contact surface runoff from areas immediately surrounding the mine site are directed to the WRTSF via the East (Johnson Creek) Diversion Channel, and to Camp Creek via the West (Camp Creek) Diversion Channel. The mine site runoff source term includes runoff from all exposed rock units from the core infrastructure portion of the mine site.

A block model was developed by Pretium for the mine site excavation area based on the five geologic units identified through surface mapping and drilling campaigns. These units are: ANDX (intermediate fragmental volcanic rock), VSF (volcanic sedimentary facies), P2 (K-feldspar bearing porphyry), P1 (plagioclase-hornblende bearing porphyry) and S3 (conglomerate) and are described in the *MA & EMA* Permits Application (Pretium, 2015). The surface waste rock units are similar to those found in the underground mine, but have slightly different metal contents and acid base accounting (ABA) characteristics. Consequently, surface materials were characterized independent of the underground block model units. The rock units exposed as a result of these excavations include ANDX, VSF, P2, P1, and S3.

Previous water quality models used SFE results from 92 lithology-specific samples to predict loads received by the WRTSF from mine site surface run-off. The Base Case and Upper Case values were derived using median and 90th percentile values Table 3-4. However, based on a review of surface runoff samples collected from mine site contact water draining into the CWP (n=10), it was noted that concentrations of most parameters were higher than those derived from the SFE data set (Table 3-4). Therefore, the source terms applied to the water quality model for surface runoff have been revised to reflect site monitoring contact water data rather than static test SFE results.

Table 3-4:
Mine site runoff source term evaluation comparing mine site contact water samples to SFE data for mine site surface rock

Parameter	Units	BC FWAL		All Data			
		Long-term	Short-term	Mine Site Contact Water Samples (n=10)		Mine Site SFE data (n=92)

Notes: Base Case and Upper Case values are based on average and maximum mine site contact runoff concentrations; NP = none proposed; BC FWAL = water quality guidelines for the protection of freshwater aquatic life (ENV 2017, ENV 2019a); values in bold italics are higher than the long-term BC FWAL; values in bold are higher than the short-term BC FWAL.

3.3.3 Surface Waste Rock

A summary of the lithology-specific surface waste rock excavation work carried out during Construction phase is provided in Table 3-5. Preliminary ML/ARD characterization designated three out of the five geologic model units for surface waste rock as NPAG based on median neutralization potential ratio (NPR) values; however, the NPR values are very close to the PAG threshold value of 2 (2.0, 2.4 and 2.6 for the S3, P2 and ANDX units, respectively). The majority of the VSF and P1 samples are characterized as PAG with NPR values generally <2. Results from confirmatory sampling of these units are consistent with the preliminary characterization. Thus, surface-blasted mine site waste rock was generally classified as PAG and all was managed through sub-aqueous deposition in the WRTSF. A discussion of the preliminary geochemical assessment and confirmatory sampling is summarized in the 2015 and 2016 Annual Reports (Pretium, 2016; 2017).

Table 3-5:

3.3.3.1 Instantaneous Loads

Lithology-specific SFE data sets were used to predict the instantaneous loads from mine site surface waste rock deposited in the WRTSF. Source terms were developed using the waste rock schedule and SFE data from preliminary characterization studies of mine site surface waste rock lithologies. The source terms for instantaneous loads to the WRTSF from submerged mine site waste rock incorporate all the available SFE data and utilize the tracked waste rock tonnages deposited in the WRTSF during the Construction phase.

Monthly loads were scaled to account for the proportion of waste rock considered to be reactive (*i.e.*, soluble) using the fraction of material that is < 6.4 mm, or approximately 20% of the total waste rock. Base Case and Upper Case source terms were calculated from the cumulative dataset using the 75th and 90th percentile lithology-specific SFE values and the scaled monthly waste rock excavation tonnages (Table 3-5). The source terms for Base Case and Upper Case instantaneous mine site surface waste rock loads are unchanged from previous models (*i.e.,* Lorax 2018; 2020) and are summarized in Table 3-6 and Table 3-7, respectively.

3.3.3.2 Post-Depositional Loads

Leachate data from saturated column kinetic tests comprising lithology-specific surface waste rock (VSF, ANDX, P2, S3) were used to assess which parameters have the potential for long term leaching behaviour after deposition in the WRTSF. Based on the assessment, As and Sb were identified as parameters showing longer-term release patterns. Post-depositional loads for these parameters were calculated using stabilized column leachate concentration data combined with the surface waste rock schedule (Table 3-5) and assumptions regarding waste rock reactivity. In reality, the loads contributed to the WRTSF would be controlled by molecular diffusion; however, waste rock sequencing information is not available, therefore the approach used to derive post-depositional As and Sb loads is based on lithology-specific loading rates.

Median and 90th percentile leachate concentration values were used to derive Base Case and Upper Case loading rates. Loading rates (mg/kg/month) for each surface waste rock lithology were multiplied by the respective lithology-specific cumulative waste rock tonnages (Table 3-5) to derive monthly post-depositional loads. Leachate quality from the P2 column was used as a surrogate for the P1 unit when calculating the potential contributions from the P1 waste rock tonnages deposited in the WRTSF. It is assumed that any waste rock deposited in the lake will contribute post-depositional loads for approximately one year following placement. It is expected that most of the waste rock dump subaqueous exposed faces will be covered within one year through ongoing deposition of waste rock, thereby burying the underlying layers and limiting post-depositional leaching.

No revisions to these terms were applied to this model update since most of the waste rock was placed in the WRTSF over 6 years ago, significantly longer than the assumed time period over which diffusional loads would be released to the WRTSF. Furthermore, no surface waste rock characterization data has been collected to warrant further revision to these terms. Base Case and Upper Case As and Sb post-depositional loads are summarized in Table 3-8, along with the total cumulative waste rock tonnages susceptible to leaching.

Table 3-6:
Base Case mine site waste rock deposition source term loads (g)

3.3.4 Weathered Surface Material

Weathered surface material was excavated from the mine site surface in preparation for operations. A summary of the tracked tonnages of weathered surface material placed in the WRTSF by deposition month is provided in Table 3-9.

Table 3-9:
Tracked tonnages of weathered surface material deposited in the WRTSF

Aug-17	504
Sep-17	442
Oct-17	56
May-18	208
Total	110,896

Soil size weathered parent materials were salvaged, as feasible, during construction and stockpiled as required by MEMPR for potential use in mine reclamation; a total of 30,000 m^3 was stockpiled. A geochemical surficial materials characterization program completed during construction in 2015 indicated however that these materials have a high PAG potential and elevated metal concentrations (*e.g.*, As levels (21-446 ppm) exceeding the CCME guideline of 12 ppm), and have high coarse fragment content, generally low organic matter content and limited soil development. Other weathered surficial materials that were not feasible to salvage due to shallow depth over bedrock, terrain and other constraints, and particularly materials dominantly comprised of broken rock, were deposited in the WRTSF. Details of the 2015 geochemical characterization program and an overview of the baseline studies are provided in the 2015 Annual Report (Pretium, 2016).

SFE data were used to predict the instantaneous loads from mine site weathered surface material deposited in the WRTSF. Given the relatively fine particle size distribution of the surficial material, all the material is considered reactive (*i.e.*, soluble). Base Case and Upper Case source terms were calculated from the cumulative dataset using median and 90th percentile SFE values, respectively, and the monthly excavation schedule (Table 3-9). The source terms for Base Case and Upper Case are summarized in Table 3-10 and Table 3-11, respectively.

Table 3-10:
Base Case weathered surface material source term loads

3.4 Underground Mine

3.4.1 Overview

Based on the mine plan represented in this model update, approximately 8.0 Mt of waste rock will be generated over LOM as the underground mine is developed. A portion of this waste rock will be placed as rock backfill in the underground mine, with the rest to be deposited in the WRTSF under permanent water cover, as prescribed by the mine plan.

Materials backfilled into the underground mine – in addition to wall rock exposures, paste bleed water, and infiltrating groundwater – will contribute a geochemical load to underground mine water. This section describes the geochemical source terms for underground mine water and the loads associated with waste rock produced from the underground mine that will ultimately be stored in the WRTSF.

3.4.2 Underground Mine Waste Rock

The total mass of waste rock generated from the underground mine during the LOM is estimated to be 8.0 Mt, with 4.6 Mt of waste rock excavated having already been excavated (as of December 2021). Waste rock generated during operations will be managed through subaqueous deposition in the WRTSF and/or backfilling in the underground mine. A previous water quality model assessed two end-member waste rock deposition scenarios – one with maximized deposition in the WRTSF, and one with maximized backfill placement. The results for the two modelled scenarios were very similar and thus this model presents only the expected deposition scenario, recognizing that this may change.

Source terms were developed for: 1) underground mine waste rock deposited in the WRTSF; and 2) contact water from the underground mine. Underground waste rock terms were derived for both instantaneous and post-depositional loads (as described in Section 3.3.1), along with loads associated with sub-aerial exposure of waste rock while stored on surface before being deposited into the WRTSF.

Preliminary ML/ARD characterization of underground mine waste rock (464 pre-2016 samples) showed that the vast majority of samples are PAG (NPR < 2). The confirmatory sampling program was developed to monitor the geochemistry of rock excavated from the underground mine and assess any potential variation from the initial characterization of the defined geologic model units. Confirmatory sample results to date are generally consistent with prior characterization results, with the majority of samples indicated to be PAG (Pretium, 2020d). Given the PAG designation, all waste rock from underground is scheduled to be deposited in the WRTSF and/or backfilled in mined out stopes of the underground mine below the post-closure water table. *Mine Act* Permit M-243 limits subaerial exposure of waste rock to be deposited in the WRTSF to a maximum of 2 years. Summaries of the geochemical assessment and confirmatory sampling results are provided

in the ML/ARD Review and Update (Pretium, 2020d) and well as the subsequent annual reports (Pretium, 2021; 2022a).

Lithology-specific underground mine waste rock schedules have been developed as per the mine plan. The underground waste rock geologic model units defined for water quality modelling purposes are:

- VSF (volcanically-derived siltstone and sandstone);
- ANDX (latite to andesite fragmental volcanics);
- Conglomerate (cobble to boulder conglomerate with sandstone);
- Office P1 (hornblende, feldspar phyric latite flows);
- Office P2 (plagioclase, K-feldspar, hornblende porphyry); and
- Silicified Cap (silicified heterolithic conglomerate, sandstone and mudstone).

The schedule for underground waste rock placement in the WRTSF is presented in Table 3-12, whereas the underground mine backfill waste rock schedule is presented in Table 3-13. Both schedules are based on the mine plan represented in this model update. Loads were calculated for the instantaneous release, diffusive release, and potential leaching due to exposure on the waste rock deposition pad. Loads associated with backfilled waste rock are presented in Section 3.4.3 along with other mine water components.

Table 3-12:
Lithology-specific waste rock schedule for waste rock to be placed in the WRTSF

Year	Conglomerate	Fragmental	Office P1	Office P2	Silicified Cap	VSF	Total waste rock placed in WRTSF

Total (LOM)	**570**	**1574**	**663**	**5**	**153**	**3455**	**6420**

Note that actual schedules are presented for 2015-2021, whereas projected schedules, as prescribed by the mine plan, are presented for 2020-2029.

Table 3-13:
Lithology-specific waste rock schedule for waste rock to be backfilled in the underground mine

Year	Conglomerate	Fragmental	Office P1	Office P2	Silicified Cap	VSF	Total waste rock placed as backfill
	(kt)	(kt)	(kt)	(kt)	(kt)	(kt)	(kt)
2018	n/a	n/a	n/a	n/a	n/a	n/a	28
2019	n/a	n/a	n/a	n/a	n/a	n/a	22
2020	n/a	n/a	n/a	n/a	n/a	n/a	66
2021	n/a	n/a	n/a	n/a	n/a	n/a	102
2022	4	32	32	0	1	163	231
2023	8	73	57	0	2	101	241
2024	16	60	28	1	2	67	173
2025	41	43	46	2	2	92	225
2026	31	32	43	0	4	109	220
2027	35	19	30	0	2	86	172
2028	0	16	5	0	1	38	59
2029	4	21	3	0	0	28	57
Total (LOM)	**139**	**295**	**243**	**3**	**13**	**685**	**1596**

Note that waste rock backfill is not currently tracked by lithology and thus the backfill placed in the underground mine between 2018 and 2021 is presented as a total. No waste rock was placed as backfill prior to 2018. The backfilled values presented for 2022 through 2029 are based on the mine plan and thus are lithology specific.

3.4.2.1 Instantaneous Loads

Lithology-specific SFE data sets combined with waste rock deposition schedules were used to predict the instantaneous loads from underground waste rock deposited in the WRTSF, as described in Section 3.3.3.1 for surface waste rock. The source terms for instantaneous loads to the WRTSF from submerged underground waste rock incorporate all available SFE data and utilize the tracked waste rock tonnages deposited in the WRTSF (through to the end of 2021), as well as the projected waste rock schedules (Table 3-12).

Monthly loads are scaled to account for the proportion of waste rock considered to be reactive (*i.e.*, soluble) using the fraction of material that is < 6.4 mm, estimated to be approximately 40% of the total underground waste rock. The proportion of reactive fines assumed for the waste rock is based on particle size distributions completed for representative subsamples from field bin and saturated column tests.

Base Case and Upper Case source terms were calculated from the cumulative dataset using the median (or 75th percentile in some cases to be consistent with observed lake quality) and 90th percentile lithology-specific SFE values and the scaled annual waste rock excavation tonnages (Table 3-12), assuming that waste rock is placed in the WRTSF during ice free months only (June-November). Base Case and Upper Case source terms for waste rock submerged in the WRTSF are presented in Table 3-14 and Table 3-15, respectively.

Table 3-14:
Base Case underground waste rock instantaneous loads (g)

An additional term was developed to account for unclassified underground mine waste rock, termed 'heavy waste', which was placed in the WRTSF between April 2019 and February 2020 (~94 kt), and which will be placed in the WRTSF by October 2023 (~71 kt). The heavy waste placement schedule applied to the water quality model is presented in Table 3-16. The instantaneous loads associated with deposition of this material were derived from SFE data (n=10), following the same approach as outlined above for waste rock. Base Case and Upper Case source terms for heavy waste in the WRTSF are presented in Table 3-17 and Table 3-18, respectively.

3.4.2.2 Post-Depositional Loads

Leachate data from saturated column kinetic tests comprising waste rock from the underground mine (VSF, Fragmental and Conglomerate) were used to assess which parameters have the potential for longer-term leaching behaviour. Based on the assessment, As and Sb were identified as parameters showing longer-term release patterns. These are the only parameters for which a post-depositional load is applied. Post-depositional loads for these parameters are based on stabilized waste rock column leachate concentration data (*i.e.*, last five analyses, up until December 2021) combined with the underground waste rock schedule (Table 3-12) and assumptions regarding waste rock reactivity.

Following the approach applied in previous models, median and 90th percentile leachate concentration values were used to derive Base Case and Upper Case loading rates. Loading rates (mg/kg/month) for each underground waste rock lithology were combined with the lithology-specific tonnages presented in Table 3-12 to derive updated monthly loads released to the WRTSF. Leachate quality from the surface P2 column was used as a surrogate for the underground Office P2 and Office P1 units when calculating the potential contributions from these waste rock tonnages deposited in the WRTSF. Leachate quality from the acid generating S3 column was used as a surrogate for the Silicic Cap. It is assumed that any waste rock deposited in the lake will contribute post-depositional loads for approximately one year following placement. After this time, it is assumed that on-going deposition of waste rock from development of the underground mine will limit post-depositional leaching. Base Case and Upper Case As and Sb predictions for post-deposition loads are summarized in Table 3-19.

The contribution of post-depositional loads is projected to continue throughout the closure and post-closure periods. Ultimately, final tailings production and natural sedimentation in the WRTSF are assumed to cover the final waste rock deposits and inhibit further contaminant release.

Table 3-19:
Underground waste rock post-deposition loads (g)

Year	D-Sb		D-As

Closure and post-closure	2	2	17	20

3.4.2.3 Surface Exposure Loads

Most of the underground waste rock brought to surface will be deposited in the WRTSF immediately; however, a portion may be stored at surface for up to two years prior to subaqueous deposition as per *Mines Act* Permit M-243 Condition D.3(c)(v). The exposed surface portion of the waste rock pad develops as waste rock is added to the pad and waste rock is deposited into the WRTSF. Subaerially exposed PAG pad materials may be replaced with either NPAG or fresh PAG materials within the two-year time frame, or the surface PAG materials may be excavated and deposited in the main body of the lake, leaving shallow ponded areas within the pad (geotechnical and other conditions apply to these activities).

Accumulated loads associated with exposure of waste rock over a two-year time frame have been incorporated into the Brucejack Mine water quality model. Proportional loads from the four major geological model units (representing 97% of waste rock to be excavated from the underground mine; Table 3-12) were determined based on field bin leachate results (as presented in the 2016 Annual Report; Pretium, 2017) and the estimated maximum volume of waste rock to be subaerially exposed on the waste rock platform at any given time (~180,000 m^3). The total loads accumulated over a two-year time frame,

along with the monthly loads for May-October (*i.e.*, the months when leaching would be anticipated), are presented in Table 3-20. These data, along with the approach applied for derivation of surface exposure loads, have been reviewed and based on this assessment, no updates were made to this term for this model.

Table 3-20:

3.4.3 Underground Mine Water

The underground mine water source term represents the cumulative geochemical load of wall rock, groundwater, paste backfill and rockfill in the underground mine workings. Loading rates associated with each of these mine components are developed in this section, along with solubility controls for underground mine water. Source terms are developed for three distinct periods of mine life: operations, closure, and post-closure.

During operations, mine workings are actively dewatering and expanding. Source terms for each of the mine components (wall rock, rockfill, paste backfill) are calculated by upscaling kinetic tests. In the case of wall rock, loading rates are scaled by calibration to site monitoring data. The geochemical loadings generated from the underground mine will increase throughout operations as mine workings expand and PAG exposures gradually become acid generating. Loads from paste backfill bleed water and blasting residues in the mine underground are discussed in Sections 3.6.6 and 3.8.5, respectively.

At closure, mine workings will be flooded over an estimated seven month time period and are predicted to reach a final water elevation of approximately 1393 masl to 1407 masl, averaging 1401 masl. For the purpose of source term calculation, an elevation of 1380 masl is conservatively applied (1380 masl would have higher wall rock exposures and associated loadings). Submergence of mine workings will release an initial flush of water-soluble oxidation products stored on mineral surfaces, termed 'flushing loads'. This flushing load along with continued oxidation of unsaturated mine workings will result in elevated loading during mine flooding. Water quality during closure will be mitigated by accelerated flooding and re-circulation of mine water through the WTP as described in the 4950 tpd groundwater model report and water balance model report (Lorax, 2023a and 2023b, respectively). This will reduce metal concentrations in mine water during flooding, for parameters that are treated by the WTP, and accelerate stabilization of the mine pool (*i.e.*, the water present in the underground mine).

The post-closure source terms define the long-term geochemical loadings that will emanate from the underground mine. Loading sources to the mine pool in post-closure will originate from continued oxidation of unsaturated mine workings above the water table, and residual loadings from saturated mine workings.

3.4.3.1 Background Groundwater

The background groundwater source term is applied to groundwater infiltrating into the mine workings during operations. This source term is meant to represent groundwater before it interacts with the underground mine. During closure and post-closure, this source term is re-assigned to the saturated concentration source terms defined in Section 3.4.3.2.3.

This change is made to reflect the potential for groundwater moving through flooded mine workings to pickup a geochemical load through interaction with wall rock, rockfill and paste backfill.

The groundwater source term is based on water quality monitoring of adit drainage from time periods when mine workings were flooded. Nearly all of the mine workings excavated by Newhawk were saturated, making the adit drainage prior to dewatering in October 2011 representative of local groundwater in the mining area. The median concentrations observed in adit drainage from October 2009 to October 2011 were used for the background groundwater source term with some minor modifications (Table 3-21). The concentration of pH-sensitive parameters (*e.g.,* Ca, Mg, Co, Mn, P, Sr and Zn) were observed to decline when pH increased shortly after mine workings were dewatered. For example, D-Zn concentrations ranged from 0.007 mg/L to 0.046 mg/L when mine workings were flooded and have declined to 0.001 mg/L to 0.0068 mg/L (median 0.002 mg/L) when mine workings were dewatered. This poses a challenge for model calibration, which scales wall rock loading rates to reproduce observed underground water quality. Improved method detection limits (MDLs) after October 2011 for Be, Bi, Cd, Cu, Fe and Hg present another challenge. To support a conservative model calibration, the minimum concentration of these parameters once dewatering commenced is applied to background groundwater chemistry in operations. Background groundwater chemistry used in the water quality model is unchanged from previous models and shown in Table 3-21. Note that no distinction is made between Base Case and Upper Case background groundwater water quality for the purpose of the water quality model.

3.4.3.2 Unsaturated Underground Mine Source Terms

The unsaturated underground mine source terms were developed following the approach outlined in previous water quality model reports (Pretium, 2015; Lorax, 2018; Lorax, 2020c). The only updates incorporated into unsaturated mine components are additional kinetic test results and the 4950 tpd waste deposition schedule.

The unsaturated underground mine source terms are applied in all phases of mine life. Loading rates are defined per tonnage of rockfill and paste backfill or surface area of wall rock. The surface area and tonnage of these mine components increase throughout operations as defined by the mine plan. During closure, the total loading from unsaturated mine workings declines as the water table rises and submerges mine workings. The same loading rates (per unit area or tonnage) are applied during the operations and closure phases. However, the post-closure loading rates are modified so that only the final humidity cell cycles (median of final 5 cycles) are used to estimate long term loading rates.

3.4.3.2.1 Wall Rock Loads

The wall rock loading rate represents the geochemical load produced from oxidation of wall rock exposures as a function of time. The wall rock source term is calculated by multiplying lithology-specific humidity cell loading rates (units of mg/kg/wk) by wall rock conversion factors (units of kg/m^2) which produce area-normalized wall rock loading rates (units of $mg/m^2/wk$). This loading rate is then calibrated using site monitoring data by adjusting the wall rock scaling factor. The development of this term follows the same approach as outlined in previous water quality models developed for the site (Pretium, 2015; Lorax, 2018; Lorax, 2020a). Updates in the current model iteration are limited to incorporation of additional humidity cell test results and the updated mine schedule.

The wall rock exposure schedule is shown in Table 3-22. This schedule shows the annualized wall rock exposures as well as the area exposed above an elevation of 1380 masl which is assumed to remain unsaturated during post closure. The humidity cells used to represent different wall rock lithologies are shown in Table 3-23. Source term calculations apply the 75th percentile loading rate for Base Case and the 90th percentile loading rate to the Upper Case. The post-closure source term uses the median loading rate of the final 5 cycles. The HCT loading rates and wall rock exposure areas are multiplied by the wall rock conversion factors developed in Lorax (2020a) shown in Table 3-24, to produce wall rock source terms for operations and closure (Table 3-25 and Table 3-26, respectively).

Loading rates have been updated using data generated through January 17th, 2022 for ongoing kinetic tests (HC20, HC21, HC23, HC25, HC28, HC29, HC31, HC32, HC34, HC36).

Table 3-22:
Cumulative wall rock exposures over mine life

Mine Year	P1	VSF	S3	ANDX	P2	SILCAP	Total

3.4.3.2.2 Rockfill Loads

Waste rock backfill (rockfill) will contribute a geochemical load to the underground mine. The projected amount of rockfill that will be placed into mine workings over life of mine is shown in Table 3-13. The rockfill source term is based on lithology-specific humidity cell data scaled to reflect field conditions following the approach outlined in the *MA & EMA* Permits Application (Pretium, 2015). The only updates to the current rockfill source term from previous model iterations are incorporation of ongoing kinetic test results through January 17th, 2022, and the rockfill mass based on the 4950 tpd mine schedule.

Humidity cell loading rates are scaled to reflect the differences in field and laboratory conditions using 'scaling factors'. A summary of the scaling factors used to convert laboratory loading rates to field loading rates for underground mine rockfill are presented in Table 3-27. These scaling factors are based on first principles and physicochemical properties that impact mine waste weathering. Note that these are the same scaling factors used in previous versions of the water quality model (Pretium, 2015; Lorax, 2018; Lorax, 2020a)

Table 3-27:
Scaling factors applied to humidity cell loading rates to predict rockfill source term

Scaling Factors	*Base Case*	*Upper Case*
Temperature Correction	0.3	0.3
Contact Water Factor	0.5	1.0
Grain Size Correction Factor	0.2	0.2

Scaling factors used to convert laboratory humidity cell weathering rates to field conditions include a temperature correction, a contact water factor and a grain size correction factor. Sulphide oxidation rates are temperature sensitive; therefore, the temperature difference between laboratory and field conditions is predicted based on an Arrhenius relationship used to derive the 'temperature correction' scaling factor. Humidity cells are designed to achieve complete flushing of mineral surfaces, ensured by the small sample size (1 kg) and high flushing rate (0.5 L/week). This high flushing rate inhibits oxide accumulation on mineral surfaces in humidity cell tests. In unsaturated waste rock, a portion of oxidation products will accumulate on mineral surfaces, particularly in areas of the rock fill which are poorly flushed. To account for this accumulation of weathering products on mineral surfaces associated with insufficient rinsing, a 'contact water' scaling factor is introduced. Drill core samples used for laboratory kinetic testwork are ground to a relatively fine grain size (< ¼"), hence, material used in humidity cells have a greater surface area to mass ratio than is expected for waste rock. The grain size scaling factor reflects differences between

grain size in humidity cell tests and in the field. For an explanation of the selected scaling factor values shown in Table 3-27, see Pretium (2015).

The same humidity cell groupings that were used in calculating the wall rock source term were applied to the waste rock backfill source term. Median and 90th percentile loading rates were used to estimate the Base Case and Upper Case rock fill source terms, respectively. The scaled waste rock backfill loading rates used to calculate the updated underground mine water source term are provided in Table 3-28.

Upon mine closure, backfilled waste rock will be submerged below the final water table to mitigate the long-term potential for ARD development, as per Condition D.3(c)(iii) in *Mines Act* Permit M-243. As such, no unsaturated waste rock backfill term has been developed for post-closure.

Table 3-28:

3.4.3.2.3 Paste Backfill Loads

During operations, paste backfill is placed in underground voids for ground support. The schedule for placement of paste backfill to the underground mine is provided in Table 3-39.

The unsaturated source term for paste backfill is derived by scaling humidity cell loading rates to field conditions, as described in the *MA & EMA* Permits Application (Pretium, 2015). Subsequent model updates incorporated: (1) HCT results on paste tailings collected from site (T18) which superseded older kinetic testing which used metallurgical paste tailings samples (T12), and (2) development of a calibrated hexavalent Cr loading term to more accurately predict behaviour associated with cement addition (Lorax, 2020c). Updates to the current source term iteration include incorporation of ongoing kinetic test results from T18 through January 17th, 2022, and the paste backfill mass based on the 4950 tpd mine schedule.

Median and 90th percentile loading rates were used to estimate the operations Base Case and Upper Case paste backfill loading rates, respectively. The post-closure source term for paste backfill uses the median loading rate of the final 5 cycles. The humidity cell loading rates are scaled using the same scaling factors described in the *MA & EMA* Permits Application (Pretium, 2015) to relate the laboratory kinetic test to field conditions. The scaling factors are shown in Table 3-29, and are meant to reflect differences between laboratory and field conditions, as described in 3.4.3.2.2. Justification for the selected scaling factor values can be found in Pretium (2015). The loading rates applied to paste backfill in the water quality model during operations and closure are shown in Table 3-30.

Table 3-29:
Scaling factors applied to humidity cell loading rates to predict paste backfill source term.

3.4.3.3 Saturated Underground Mine Source Terms

Active flooding of the mine at closure will submerge approximately 78% of the paste tailings, 85% of the wall rock exposures and 100% of the rock fill assuming a minimum water table elevation of 1380 masl. As these mine components are submerged, an initial 'flushing' load will be released, followed by longer-term saturated loads which will continue to be released in post-closure. The saturated underground mine source term follows the same approach described in Lorax (2020c). Updates to the source term in this model iteration are: (1) limited addition of additional kinetic testing incorporated into the paste backfill and rockfill loading rates described in previous sections, and (2) changes in the volume and elevation of mine waste deposition and wall rock exposures based on the 4950 tpd mine plan.

3.4.3.3.1 Flushing Loads

The flushing loads are calculated by estimating the rate that a geochemical load accumulates on rockfill, paste backfill and wall rock when mine workings are unsaturated during operations. The rate of accumulation is estimated from scaled kinetic testing data, while the duration of exposure is estimated from the mine schedule. These loads are assumed to be instantaneously released as the water table rises and mine workings become flooded at closure.

Paste backfill and rockfill mineral surfaces are only partially rinsed with infiltrating mine water during operations. This is reflected in the 'contact water' scaling factor used to produce unsaturated loading rates for these mine components in section 3.4.3.2. The Base Case unsaturated source terms for rockfill and paste backfill assume that 50% of mineral surfaces are effectively rinsed by infiltrating mine water during operations (Table 3-27 and Table 3-29). To calculate the flushing load, it is assumed that the 50% of mineral surfaces that are not effectively rinsed will accumulate a geochemical load at the same rate as mineral surfaces that are rinsed. That is, the 50% of mineral surfaces that are not effectively rinsed during operations will accumulate and contribute to the flushing load at the same rate that the 50% of mineral surfaces that are well rinsed contribute to the unsaturated load. Hence, the rate that a geochemical load accumulates on paste backfill and rockfill mineral surfaces is equal to the geochemical loading rates shown in Table 3-28 and Table 3-30.

Mineral surfaces which contribute to the wall rock source term include bedrock fractures, muck on the mine floor, and wall rock surface exposures themselves. It is assumed that fractures and muck on the mine floor will be relatively well rinsed with infiltrating mine water during operations compared to actual wall rock exposures which are only periodically rinsed by groundwater seeps or drilling water. The initial flush of wall rock is calculated from loading rates observed at wall washing stations. The median loading rate and 90th percentile loading rate are applied to the Base Case and Upper Case source terms, respectively. These loading rates are monitored in the field, and already normalized for wall rock surface area. Therefore, no scaling factors are applied to the accumulation rate of this geochemical load. The rate that geochemical loads accumulate on wall rock exposures are shown in Table 3-31. Note that wall rock washing stations have not been established for minor lithologies (*e.g.*, P1 and silicified CAP). Therefore, the average Base Case and Upper Case accumulation rates observed at wall rock stations established on major rock types (S3, ANDX and VSF) are applied to these lithologies.

The amount of time that the flushing load accumulates on mineral surfaces prior to submergence is defined by the mine schedule (Table 3-13, Table 3-22 and Table 3-39). That is, rockfill placed in 2023 will accumulate a flushing load for 7 years, while rockfill

placed in 2029 will accumulate a flushing load for 1 year prior to flooding in 2030. The average flushing load per unit mass or area of rockfill, paste backfill and wall rock at the end of mine life are shown in Table 3-32.

The timing and extent of mine workings that will flood at closure is a function of the rate of water table rise and the elevation of underground mine workings. The water table is expected to rise to a final elevation of approximately 1401 masl over a 7 month period in closure. During mine flooding, the amount of paste backfill, rockfill and wall rock which will be submerged is calculated on a monthly time step. Thus, the monthly flushing loads are calculated for mine workings that become flooded each month. The elevation of wall rock, rockfill, and paste backfill in the mine underground is shown in Figure 3-1. Note that a portion of mine workings in the WZ remain above the final water table of 1401 masl and is not expected to flood.

Table 3-31:
Accumulation rates of geochemical load on wall rock that will be released during initial flush

Figure 3-1: Cumulative rockfill tonnage (top left), paste backfill tonnage (top right) and wall rock area (bottom centre) as a function of elevation. Grey line shows minimum water table elevation in post closure of 1380 masl.

3.4.3.3.2 Saturated Concentration Terms

Saturated conditions will inhibit acid generation and metal leaching associated with sulfide mineral oxidation; however, some metal leaching may continue from dissolution of oxide minerals. To reflect this potential for long term metal release from saturated mine

workings, source terms are developed using saturated column data and historic observations of adit drainage from time periods when mine workings were flooded. This source term is developed using the approach applied in previous model iterations with the following updates:

- Incorporation of recent saturated column data
- Updated volume of of rockfill, paste backfill and un-backfilled 'void' space in mine workings as per the 4950 tpd mine schedule.
- Consideration of lower hydraulic conductivity of paste backfill relative to rockfill and void space.

Paste backfill and rockfill are represented using saturated column results completed on waste rock (columns 1 and 2) and tailings (columns 3 and 5). Columns 1 and 2 are ongoing so results through January 2022 are incorporated into source term calculations. The 90th percentile concentrations are applied to the Upper Case and the median concentrations of the final 5 cycles are applied to the Base Case source terms. Mine portal water quality from time periods when mine workings were flooded and passively discharging was used to represent mine workings that are not backfilled (*i.e.*, void space). No updates have been made to this term. The maximum and median concentrations of adit drainage from October 2009 to October 2011 are used to represent Upper Case and Base Case void space in the underground mine.

Chemistries representative of the three saturated mine components (rockfill, paste fill, and void space) are proportioned based on their relative volumes and hydraulic conductivity. The 4950 tpd mine plan indicates a total of 6.4 Mm^3 of rock will be excavated from below the minimum water table elevation of 1380 m. Of this volume 12% will be occupied by rockfill, 71% will be occupied by paste backfill, and 17% will be empty (not-backfilled) void space. The amount of contact water interacting with these different material types will be a function of both their abundance and the relative hydraulic conductivity of these materials. Notably, paste backfill has a hydraulic conductivity of 1.2E-8 to 5.0E-8 m/s, which is <1/10 the hydraulic conductivity of rockfill (1.0E-6 m/s) and void space (1 m/s). Therefore, groundwater will preferentially flow through the more permeable rockfill and void zones. To reflect this in the underground mine source term, the amount of contact water interacting with paste tailings is assumed to be 1/10th of its relative volume. This results in the relative proportions of the three water types being weighted as 39% rockfill, 54% void space, and 7% paste backfill, which is presented in Table 3-33. This source term is applied to groundwater which interacts with saturated mine workings during the closure and post-closure phases.

3.4.3.4 Underground Mine Water Source Term Evaluation

The following sections describe refinements made to the underground mine water source terms. These refinements consider the potential for acid generating from PAG rockfill and wall rock exposures, solubility control. The approach for these model considerations has not been updated from previous model iterations (Pretium, 2015, Lorax 2018 and Lorax 2020c).

3.4.3.4.1 Potential for Acid Generation

During mine operations, gradual acidification of unsaturated PAG rock exposures will occur in the mine underground. The rate at which wall rock and rockfill becomes acidic is described in Appendix 4-B4 of *MA & EMA* Permits Application (Pretium, 2015). Subsequent operational monitoring found the Upper Case acidity assumptions to be overly conservative, and therefore lag time calculations originally developed for the Base Case were applied to the Upper Case scenario. This update is discussed in Lorax (2020c).

During operations and closure, the % of acidic wall rock and rockfill lithologies are calculated as a function of exposure time (S3 and ANDX) (Figure 3-2), or as a constant value (P1, VSF, P2, SILCAP) (Table 3-34) (Pretium, 2015). In the post-closure scenario, it is assumed that the percentage of each wall rock unit which has an NPR<2 becomes acid generating (Table 3-34). All rockfill will be submerged in post-closure, so this assumption only applies to remaining wall rock above the final water table.

Figure 3-2: Percent of S3 and ANDX wall rock and rockfill exposures predicted to become acid generating as a function of exposure time.

Table 3-34:
Percent of wall rock and rockfill exposures assumed to be acid generating by lithology in operations, closure and post-closure.

Rock Type	Operations and Closure	Post Closure
P1	0%	19%
VSF	5%	84%
S3	Function*	80%
ANDX	Function*	57%
P2	0%	0%
SILCAP	30%	30%

*Acid generation potential calculated as function of exposure time

Monitoring of seep and sump water in the mine underground can provide an early indicator of development of ARD and can support validation of the lag time calculations originally developed in Pretium (2015) shown in Figure 3-2 and Table 3-34. Routine monitoring of seeps and sumps was initiated in 2016 with sampling occurring on a quarterly basis as outlined in the mine's ML/ARD Management Plan (Pretium, 2020a). Out of the 76 distinct seeps that have been sampled, only 4 (Seep 7, Seep 44, Seep 53 and Seep 56) have shown acidic pH values (<6.0 pH) (Figure 3-3; Pretium, 2022a). Three of these seeps (Seep 7, 44, and 56) have shown intermittently acidic seepage. That is, these seeps have rebounded to neutral pH after acidic pH values were initially observed. The only seep that shows persistent acidic seepage is Seep 53. This seep has remained acidic on all nine sampling events that occurred between April 2019 to December 2021, with pH values ranging from 2.7 to 4.4 pH.

Monitoring of underground sumps have shown consistently neutral to alkaline pH (ranging from pH 8.3 to pH 11.6). This shows that bulk underground mine water remains alkaline in and confirms that the acidity load from acidic seeps in the mine underground is not sufficient to cause pH instability in sump water.

The acidic seeps are all hosted in ANDX wall rock exposures. This rock type is relatively abundant in the mine underground (29% of exposures as of December 2021), and has a higher ARD potential than VSF which constitutes a majority of the existing wall rock (Table 3-22). Lag time calculations predict that by the end of 2022, 3.3% of all wall rock exposures, inclusive of the 6.4% of ANDX exposures, would be acid generating.

The observation that all sumps and a majority of seeps (72 of 76) show neutral to alkaline pH data are consistent with the lag time calculations applied in the water quality model. Therefore, no updates to lag time calculations are proposed at this time. The only update incorporated into the acid generation calculations is the 4950 tpd mine plan. The percent

of rockfill and wall rock that are calculated to be acidic at the end of mine life and in post-closure are shown in Table 3-35.

Figure 3-3: Time series of pH monitoring results for seeps and sumps in the underground mine.

Table 3-35:
Percent of subaerial wall rock and rock fill predicted to be acidic at the end of operations and post-closure scenarios.

	End of Operations	Post-closure
Rock Fill[1]	5.3%	-
Wall Rock	6.2%	67%

[1]All rock fill will be submerged at the end of mine life, mitigating the potential for acid generation from rock fill in the post-closure scenario.

3.4.3.4.2 Solubility Controls

Solubility controls were developed for composite underground mine water. Solubility controls are based on surface sorption, secondary mineral formation, and empirical observations of monitoring data. The details of solubility control derivation are presented in the 2020 update water quality model report (Lorax 2020a), with a summary provided in Table 3-36. These solubility controls assume aerobic conditions and are therefore not applied to saturated mine workings during post-closure. The solubility controls are applied to composite drainage during operations, closure and to the portion of mine drainage originating from unsaturated mine workings in post-closure. The solubility controls described herein were originally developed in previous model iterations. No updates are introduced to the solubility controls for the 4950 tpd model iteration.

Table 3-36:
Solubility limits applied to unsaturated mine workings

Parameter	Units	Base Case	Upper Case	Solubility Control
SO_4	mg/L	-	1848	Mineral Precipitation – Gypsum [$CaSO_4 \cdot 2H_2O$]*

*Gypsum solubility limit is only reached in Upper Case source term.
**Aluminum concentrations are controlled by gibbsite in Base Case and basaluminite in Upper Case source terms

3.4.3.4.3 Validation of the Underground Mine Water Predictions

The updated underground mine water predictions applying the various revisions described above have been reviewed and compared to water quality monitoring data sets collected between 2015 and 2022. This comparison combines the water balance (Lorax, 2023b) results with geochemical loadings described herein to generate the Upper Case and Base Case mine water concentrations shown in Figure 3-4 and Figure 3-5. The current model predictions for key parameters show good agreement with monitoring data; therefore, no updates to source term calibration are proposed at this time.

Figure 3-4: Time series plot showing modelled and measured mine water concentrations of D-Cu, D-As and SO_4 from January 2015 to December 2022.

Figure 3-5: Time series plot showing modelled and measured mine water concentrations of D-Sb, D-Se and D-Mo from January 2015 to December 2022.

3.4.3.4.4 Updated Underground Mine Water Source Terms

Final source term predictions for operations, closure and post-closure for the mine underground are summarized in Table 3-37. This table shows the maximum concentrations predicted during operations, closure, and post-closure. The operations source term combines the loadings from rockfill, paste tailings, wall rock, groundwater, paste bleed water, blasting residues and re-circulated drill/dust suppression water from the fresh water

tank. Concentrations during the closure are planned to be mitigated by re-circulation of mine water through the treatment plant, as described in Lorax (2023b). Post-closure concentrations will stabilize as the initial flush is rinsed from the system, and gradually decline owing to the limited amount of mine workings that remain above the final water table elevation.

Table 3-37:
Maximum source term concentrations predicted for underground mine water during operations, closure and post-closure

3.5 Water Treatment Plant

3.5.1 Overview

The WTP is located within the mill building and receives and treats underground mine water from mine dewatering, CWP water and recycled process water from the mill, and is designed to treat influent flows of 3,120 to 10,000 m^3/day. The overall WTP water balance is shown in Figure 3-6. The water treatment design, metals and solids removal processes, and effluent design criteria are described in the 2015 *MA & EMA* Permits Application (Pretium, 2015); a summary is provided in Section 2.5.3 of the 2020 Mine Plan and Reclamation Program Update (Pretium, 2020c). Key components of the WTP treatment process include a pre-treatment clarifier (for coarse total suspended solids (TSS) removal), primary metal precipitation stage (dissolved metal and TSS removal), secondary metal precipitation stage (for dissolved metal oxy-anion and TSS removal), final metal polishing by filtration (for small particulate TSS removal) and final pH adjustment as shown in Figure 3-7. The WTP is expected to continue operating into the closure phase until active water treatment is no longer required.

Figure 3-6: Schematic of the WTP water balance

Figure 3-7: Schematic of the Brucejack Mine clarifier and WTP treatment process (green boxes represent the WTP components)

As shown in the WTP flow diagram in Figure 3-7, water requiring treatment is directed to the pre-treatment clarifier to remove TSS by gravity settling, with the clarifier overflow directed to the WTP Influent. The primary metal precipitation stage is designed to use ferric sulfate and sodium sulfide for metal precipitation, whereas the secondary stage is configured for ferric sulfate only. The operations WTP began operating in mid-2017 and ferric sulfate has been successfully used for metal removal in both stages since that time. The combined influent water quality has been monitored in the Clarifier overflow since May 2018. Influent concentrations of most dissolved parameters targeted by treatment are below WTP effluent limits (*i.e.*, Ag, Cd, Co, Cu, Fe, Pb, Mn and Zn), or are effectively treated with ferric sulfate (*i.e.*, Al, As) therefore sodium sulfide treatment has not been activated. The sulfide circuit will be commissioned for use if needed to meet PE-107835 discharge requirements. The treatment efficiency of the sulfide circuit has been evaluated by Pretium for batch treatment at small volumes and was found to be effective at removing dissolved metals targeted for treatment.

The operational treatment flows measured by the Clarifier overflow totalizer for the 2018 through 2021 period range from 825 to 9,372 m^3/day with a median value of 4,948 m^3/day (Figure 3-8) and, overall, are within the design flows of the WTP. On an annual basis, a generally increasing trend is observed in the treatment flows from 2018 to 2021 (4,532 to 5,592 m^3/day, respectively, median values) due to increased mine dewatering flows during this period (Lorax, 2023b). The highest daily WTP flows are typically observed in May through November, reflecting the seasonal influence of increased groundwater infiltration into the mine void and runoff accumulation in the CWP.

The WTP flows are modelled to increase as the mine void expands, and on an annual basis, the flows are modelled to stabilize in 2025 at approximately 7,500 m^3/day (median value) and range from 2,902 to 12,566 m^3/day during operations. The daily influent flows are modelled to peak at levels above the WTP design flow (10,000 m^3/day) for a few days in June of each year. For the modelling of treatment efficacy, it is assumed that influent flows will remain within the WTP design specifications through various water management strategies including temporary storage of water underground or in the CWP (the CWP is drawn down each spring prior to freshet), or reduction of WTP inflows of Mill process water.

Figure 3-8: Measured Water Treatment Plant (WTP) Influent Flows at the Clarifier Overflow Totalizer from 2018 to 2021.

Figure 3-9: Modelled Water Treatment Plant (WTP) Influent Flows During Operations (2022 through 2029).

The WTP generates a solid waste product (sludge) that requires management and disposal. The mass of the sludge produced depends on the TSS content of the influent, the chemical composition of the influent, the flow rate and the nature of the solid particles. The sludge to be produced during the operations phase is predicted to be a cumulative total of 150 kt, with average sludge generation estimated at 7 tpd. The total amount of sludge generated is estimated to represent less than 2% of the total tailings generated on-site. Sludge generated from the WTP is co-deposited with thickened tailings into the WRTSF in accordance with PE-107835 and permit M-243.

3.5.2 WTP Influent, Effluent and Treatment Level

The WTP influent quality was derived from influent flows as prescribed by the Brucejack Mine water balance and source terms developed for the contributing sources: underground mine water (Section 3.4.3), mine site runoff (Section 3.3.2) and process water (Section 3.6.5). Modelled WTP effluent quality is based on predicted influent quality and treatment removal rates that are derived from May 2018 through December 2021 operational data, or proxy data, and these are applied in the water quality model. The measured and modelled removal efficiencies for parameters that are treated in the model are shown in Table 3-38. The modelled removal rates are applied for the Base Case and Upper Case scenarios. The model assumptions are generally set at or below the observed removal efficiencies.

Table 3-38:
WTP influent and effluent water quality as well as observed treatment levels and removal efficiencies (May 2018 through December 2021).

[1] The Cu removal rate is derived from Britannia Mine proxy data (Madsen, 2007)

Monitoring of clarifier overflow was initiated in May 2018 and therefore the period from May 2018 through December 2021 was used for comparison of influent and effluent concentrations and derivation of WTP removal estimates. Operational monitoring data indicate the influent concentration of parameters targeted for treatment has been generally low with the exception of Al, As and Sb. The monitoring data from 2018 through 2021 indicate As and Al are effectively treated by the WTP (94% and 98% removal, respectively), whereas a smaller proportion of Sb is removed (55%). The measured removal efficiency for copper (73%) is influenced by low Cu concentrations in the influent,

which will have lower treatment efficiency than when influent D-Cu concentrations are higher. Observations of Cu removal at the Britannia Mine treatment plant, using a precipitation process that is comparable to the one used at Brucejack Mine indicate removal efficiencies of 99.9% for Cu (Madsen, 2007). Therefore, based on operational and proxy data, the removal efficiency for Cu is conservatively modelled at 95%. The measured treatment efficiency of Zn is relatively low (40% removal); however, this is expected for the ferric sulfate precipitation process at the low dissolved Zn concentrations that are observed in the influent (0.00265 mg/L, median concentration).

Sulfate is a component of the reagents that are added during the treatment process (*i.e.,* in ferric sulfate and sulfuric acid) and the median increase in the sulfate concentration from WTP influent to effluent is 67.5 mg/L for the 2018 through 2021 period. Therefore, the WTP is conservatively modelled to add 100 mg/L sulfate to the WTP effluent for the Base Case, and 400 mg/L of sulfate for the Upper Case scenario.

The concentration of parameters targeted for treatment are predicted to increase through operations, as are the WTP influent flows. The modelled treatment removal rates are derived from operational data when the daily treatment flows range from approximately 40% to 70% of the WTP design capacity (10th to 90th percentile of the measured flows, respectively). Therefore, the modelled removal rates are considered representative of treatment performance for flows up to the WTP design flows (10,000 m^3/hr). The treatment source terms reduce the WTP influent concentration by a proportional amount for parameters that are modelled to be treated and this approach accounts for variations in the modelled influent water quality.

3.6 Mill

3.6.1 Overview

The Brucejack Mine mill processes ore using conventional bulk sulfide flotation and gravity concentration to recover gold and silver. The mill produces a gold-silver bearing flotation concentrate which is shipped off-site for further processing. The gravity concentrate is refined on site to produce gold-silver doré ingots.

The mine production schedule used to update the water quality model is presented in Table 3-39. Tailings are managed through subaqueous deposition in the WRTSF and through placement in the underground mine as cemented paste backfill.

The mill components of the GoldSim water quality model were refined in the 2020 Update model based on revisions to mill components of the mine's water balance model and updates to source term data sets for model inputs. The inputs include:

- WTP effluent (described in Section 3.5.2);
- WTP sludge slurry, comprised of approximately 2.5% solids. The WTP sludge slurry is combined with the thickened tailings prior to discharge to the WRTSF;
- Reclaim water from the WRTSF: make-up water supplied to the mill;
- Recycled process water: water from ore processing that is treated by the WTP and circulated back into the mill process as feed water;
- Ore moisture: water that is on the surface of ore processed through the mill; and
- Tailings loads: loads added from processed ore.

The tracked outputs include the tailings slurry discharged to the WRTSF, the process water that is recycled to the mill via the WTP and paste backfill discharged to the underground mine. The following sections describe the source terms developed for the various mill components.

Table 3-39:
Projected ore and tailings schedules

Year	Ore (kt)	Tailings (kt)	Tailings to the WRTSF (kt)	Tailings to Paste Backfill (kt)
2017	684	628	523	105
2018	952	1,006	595	411
2019	1,338	1,303	823	480
2020	1,252	1,307	833	474

Total LOM	18,498	17,832	11,242	6,590

3.6.2 WTP Sludge Slurry Water

Authorization for co-deposition of sludge with tailings was issued via amendment of *Mines Act* Permit M-243 and Effluent Permit 107835 in March/April, 2017. The slurry water term is incorporated into the water quality model, where the WTP sludge slurry water is assumed to have the same composition as WTP effluent (described in Section 3.5.2). The solid WTP sludge loads released post-deposition are described below in Section 3.6.5.2.

3.6.3 Reclaim Water

The Mill water supply is supplemented by reclaim water pumped from the weir located at the outlet of the WRTSF (BJ 3.10), as authorized under Conditional Water License C500684. The water quality of reclaim water in the model is set to values predicted for BJ 3.10 by the water quality model.

3.6.4 Ore Moisture

During ore excavation, mine water from the underground workings becomes entrained in the ore muck pile. The water balance model assigns a flow to the water that is associated with ore to be processed through the mill, termed ore moisture. The water quality of ore moisture is assumed in the water quality model to be equivalent to the underground mine water quality (Section 3.4.3).

3.6.5 Tailings and WTP Sludge Loads

The physical grinding and chemical processing of ore results in the release of chemical loads into the mill's process water. These instantaneous loads are added to loads already present in process water from the various contributing sources (*i.e.*, WTP effluent, reclaim water, recirculated process water and ore moisture). The combined mill loads are discharged to the WRTSF with the tailings slurry and to the underground mine with the paste backfill. The tailings discharged to the WRTSF are co-deposited with WTP sludge, and following deposition, loads may be released to the WRTSF through diffusive processes.

The following section describes the approach for deriving: 1) instantaneous tailings loads introduced to the mill; and 2) diffusive loads added to WRTSF from tailings and WTP sludge.

3.6.5.1 Instantaneous Tailings Loads to Mill

As ore is processed through the mill, loads are released to process water. The GoldSim water quality model accounts for recycling of mill process water and tracks the changing chemistry of all flow-related mill inputs. In order to isolate the loadings associated with ore processing, a monitoring program was developed to assess soluble loads added during the grinding process within the SAG mill. Water samples are collected at the inlet and outlet of the SAG mill on a monthly basis (as described in the ML/ARD Management Plan (Pretium 2020a), with data presented in Pretium 2019; 2020b; 2021; 2022a) and have been used to develop the instantaneous tailings loads. For certain parameters, the concentrations measured in the SAG mill influent were consistently higher than the SAG mill effluent (*e.g.*, Ba, Ca, Co, Pb, Mg, Mn, Hg, P, K,Sr, Tl, Ti and U for the Base Case). In these cases,

the instantaneous tailings loadings are set to zero. The Base Case and Upper Case instantaneous tailings loads are based on the median and 90th percentile loadings (per tonne of ore processed) combined with the ore processing schedule. The Base Case and Upper Case instantaneous loading terms are presented in Table 3-40 and Table 3-41, respectively.

Table 3-40:

The instantaneous tailings loadings were calibrated by comparing the GoldSim modelled tailings effluent concentrations to measurements of tailings supernatant and process water. While most parameters show good agreement (Lorax 2020), some parameters (*i.e.*, sulfate, Cl, F, B, Co, Cr, Fe, K, Mo, Na, Se and Sr) required refinements through the application of calibration factors (Table 3-42).

Table 3-42:
Calibration Factors Applied to Modelled Tailings Effluent Concentrations

Parameter	Tailing Discharge Calibration Factor
Sulfate	2.2
Cl	1.9
F	1.7
B	1.5
Co	0.6
Cr	0.2
Fe	0.4

3.6.5.2 Diffusive Loads from Tailings and WTP Sludge to WRTSF

Diffusion-related loads from co-deposited tailings and WTP sludge to the WRTSF were estimated based on saturated column results and assumptions regarding diffusional transport. The approach for deriving these fluxes has not been updated. A brief overview of how the diffusive flux values were calculated is presented below. Additional discussion related to diffusional transport processes, contaminant behaviour and potential water quality impacts with respect to the co-deposition of sludge with tailings in the WRTSF is provided in a report (*Brucejack Gold Mine: Assessment of Long-Term Sludge Stability for In-Lake and Underground Deposition* (Lorax, 2016a)) that was submitted for the *Mines Act* Permit M-243 and Effluent Permit 107835 amendment applications approved in March/April 2017.

The rate of diffusional transport in sediment porewaters is a function of the concentration gradient, temperature, sediment grain size, porosity and solute size, and can be described by Fick's First Law (Eqn. 1):

$$Jz = \frac{Doj}{F} f \frac{dc}{dz}$$

where J_z is the diffusive flux; D^o_j = *in situ* diffusion coefficient; F = formation factor; ϕ = porosity; and dc/dz = the concentration gradient. Formation factor is a measure of tortuosity, and takes into account the convoluted path ions must follow to circumvent sediment particles (Li and Gregory, 1974). Diffusion coefficients are temperature dependent, with values increasing commensurately with temperature.

To simplify the calculations, a common diffusion coefficient (5×10^{-6} cm^2/s) was assumed for all parameters, as per values presented in Li and Gregory (1974), normalized to 5ºC. Flux calculations also assumed a formation factor of 2 (Ullman and Aller, 1982) and an estimated porosity of 0.7 for silt-sized materials. Leachate data from saturated column test TCol 14 comprising tailings and WTP sludge were used to calculate the concentration gradient (dc/dz).

Calculation of the concentration gradient (dc/dz) included the following assumptions:

- Concentration endmembers in sludge-bearing porewater were set equal to the maximum values measured in saturated column TCol 14;
- Concentration endmembers in the lake bottom water were set equal to median WRTSF concentrations measured throughout 2021 at station BJ 3.10;
- The sediment depth over which diffusion is assumed to apply is 3 cm; and
- Flux calculations do not account for sorption processes within the uppermost oxic sediment layers. This imparts a considerable degree of conservatism since a significant fraction of the upward diffusing Mn and Fe can be expected to re-precipitate as their respective oxide phases in the near-surface sediments and remove trace elements that show strong binding affinities for Fe and Mn oxide surfaces (*e.g.,* As, Cd, Co, Cu, Pb, Ni and Zn).

Derived fluxes (J_z) were used to calculate the annual diffusive load for each parameter to the lake water column by multiplying the diffusive flux ($\mu g/cm^2$/year) for each parameter by the estimated annual tailings surface area (m^2). The annual tailings surface areas are assumed to grow at a steady rate up to the final estimated tailings surface area. The model applied the same final surface area estimate as the previous model (382,250 m^2) since an updated surface area was not available at the time the model was developed. The modelled annual diffusion-related loads contributing to the WRTSF from co-deposited tailings and WTP sludge are presented in Table 3-43.

Table 3-43:
Diffusive loads from tailings and WTP sludge deposited in the WRTSF

3.6.6 Paste Backfill Bleed Water

Porewater contained in paste backfill that is not consumed during the cement curing process will be released as bleed water. The approach for derivation of the paste backfill bleed water term is the same as that presented in previous models, but the data used to develop the term has been updated.

The bleed water quality is assumed to be equivalent to the predicted mill process water composition for all parameters except Cr, which is dominantly introduced from the cement during paste generation. The predicted mill process water composition is calculated in GoldSim considering the flows and concentrations of components introduced to the mill (*i.e.*., WTP effluent, reclaim water, recirculated process water, and ore moisture), along with the loads added from the processed ore (the instantaneous tailings loads). Base Case and Upper Case process water predictions are based on the Base Case and Upper Case terms for the components introduced to the mill.

Chromium concentrations in paste backfill bleed water were calculated following the same approach to that described in the 2020 update model (Lorax 2020a), whereby values are based on the initial flushing results of paste backfill humidity cells. Base Case and Upper Case bleed water Cr concentrations were based on the median (0.00035 mg/L) and the maximum (0.0009 mg/L) concentrations observed in the first 10 cycles of humidity cell T18. The full set of results for humidity cell T18, along with all other humidity cells results, are presented on an annual basis in the Annual Reports (Pretium, 2016; 2017; 2018a; 2019a; 2020a; 2021, 2022a).

3.7 Sewage Treatment Plant

3.7.1 Overview

Domestic wastewater generated at the Brucejack Mine camp is treated and discharged to the WRTSF at depth, as authorized by PE-107835. The mine currently operates three FilterBoxx C75 STPs, each with a rated treatment capacity of 75 m^3/d. The maximum authorized discharge rate by PE-107835 is 175 m^3/d. Monitored discharge rate of treated STP effluent has been approximately 90 m^3/d. Monitored flows are used to estimate STP effluent discharge rates in the Water Balance Model.

PE-107835 requires that STP effluent quality is monitored quarterly, and only for biological oxygen demand (BOD) and TSS. In general, STP effluent has been monitoring monthly for these required parameters, as well as nutrients and anions. Analysis of metals in STP effluent was carried out five times in 2022, but metals are not part of the routine analysis of STP effluent.

3.7.2 STP Effluent

STP source terms for the 4950 tpd model were updated to incorporate combined STP effluent monitoring results collected from January 2019 through September 2022. Base Case source terms were set equal to the 75th percentile of monitoring results, whereas the 90th percentile was used for the Upper Case source terms (Table 3-44). The timeseries of STP effluent concentrations do not have any noticeable seasonality; therefore, all monitoring results were used when calculating percentiles, and the resulting source terms were applied to all months. Monitoring results less than detection limit were set equal to the detection limit for calculating percentiles.

Table 3-44:
Sewage treatment plant discharge source terms

3.8 Nitrogen Source Terms

3.8.1 Overview

Blasting residues from the use of explosives represent the dominant source of nitrogen (N) species (ammonia, nitrite and nitrate) at Brucejack Mine. The N containing residues result from non-detonated explosives and explosion gases (*e.g.*, nitrogen oxides) that condense on blasted surfaces (Pommen, 1983). The N residues are finite in contrast to geochemical mineral release to contact water. The export of N species in contact water is proportional to the amount of explosives used and rock blasted, therefore from these data N loading rates based on tonnage blasted are derived as source terms for the water quality model.

The N source terms provided here rely on the implementation of best management practices for explosives handling and blasting as described in the Nitrogen Management Plan (Pretium, 2022b). The input of N from explosives will cease at closure when blasting stops and mine flooding occurs. It is expected that the soluble N species will be released to the mine pool from walls, floors, and backfill to mine water during mine flooding.

Explosives-related nitrogen species are currently introduced to the WRTSF from WTP effluent, waste rock deposition in the WRTSF, tailings slurry discharge, NPAG Quarry rock contact water, mine site surface runoff and sewage treatment plant effluent. Nitrogen source terms arising from background inputs and STP effluent are described in Section 3.1 and Section 3.7, respectively, and are not discussed further in this section.

3.8.2 Data Sources

The source terms for N species (ammonia, nitrite and nitrate) are empirically derived from monitoring records for explosives consumption, ore and waste production, water quality and flows for the January 2015 through August 2022 monitoring period. Records were obtained from the following monitoring programs and used for source term derivation and validation:

- Water quality monitoring data collected at BJ 3.10, profiles within the WRTSF, Process Water, CWP Water, Mine Water, WTP influent and WTP Effluent stations;
- Monitoring of N loads in ore, tailings and paste solids and contact waters;
- Underground water quality monitoring at sumps, paste bleed water and wall wash stations; and,
- Operations records for explosives use, excavation quanities, ore supplied to the mill and waste and effluent discharge quantities to the WRTSF.

3.8.3 Explosives Use

At Brucejack Mine, Titan 7000 bulk emulsion explosive is used for underground blasting. Small amounts of packaged explosives are periodically used when emulsion is not appropriate. These include Dyno AP and Dyno SL and Dynosplit D. All products are ammonium nitrate (AN) based emulsion explosives products that are designed for use in wet conditions. The Titan 7000 is approximately 25% N in the form of ammonia and nitrate. Detonators and boosters are also used for blasting, however these are insignificant sources of N compared to the explosives and therefore usage is not tracked.

Development blasting methods are used to advance drifts and access tunnels for mining operations. The blasts are characterized by short rounds (approximately 4 m depth) with an open square blast face typically 5.5 by 5.5 m in dimension. Small diameter boreholes are drilled for loading explosives and the explosives use rate (powder factor) is high.

Ore is excavated from stopes using production longhole blasting methods, with large diameter boreholes, typically drilled upward or downward from an open drift and loaded with bulk emulsion. The boreholes extend as much as 30 m generally blasting a stope approximately 5 m deep, 30 m high and 15 m wide. Powder factors are low compared to development blasting.

For underground blasting, the overall blasting powder factors (PFs) for mine development (waste) and production (ore) are 1.65 and 0.92 kg/t, respectively, calculated from the period totals for explosives use and blasted rock tonnages. The monthly and overall PFs are plotted in Figure 3-10 for both development and production blasting. The monthly PFs vary significantly through the monitoring period, ranging from 0.77 to 2.93 kg/t for development and 0.70 to 1.30 kg/t for production blasting. The overall PFs for the period of record are considered better indicator of the average explosives usage for mining as the monthly values are influenced by rock conditions and other factors that may alter the PF for any single blast. A general increasing trend in the monthly production PF is observed beginning mid-2021 and is due to the transition from smaller to larger diameter (*i.e.,* 4”) blast holes that was initiated at that time. A new methodology for estimating development explosives usage was implemented January 2021 onwards and yields PF values that are generally higher than those reported from 2015 through 2020.

Figure 3-10: Monthly powder factor (PF) for the January 2015 through August 2022 period for development (waste) and production (ore) blasting.

3.8.4 Mine Site and NPAG Quarry

3.8.4.1 Overview

As indicated in Section 3.3.1 and Table 3-5, approximately 1,500 kt of waste rock was blasted and excavated from the mine site surface to develop the site for various facilities including the Mill, Truck Shop, Camp and CWP in preparation for operations. Construction of the mine site was initiated in September 2015 and continued through 2016, with the majority of excavation occurring in Q1 and Q2 of 2016 (Table 3-5). NPAG Quarry rock was used as fill for pad and road construction, as well as road surfacing, and a total of 1,114 kt of quarry rock was excavated from 2015 through 2021 (Table 3-2). A distinction is made for NPAG Quarry rock placed within the mine site which is included in the mine site runoff term, and for the NPAG Quarry rock placed outside the mine site, which is modelled to report directly to the WRTSF.

Source terms for N species are modelled as loading rates to the WRTSF from surface excavation pits, surface fill and from surface waste deposition. The surface waste rock load represents the mass of available soluble N species that is instantaneously released into solution upon contact with surface runoff or subaqueous deposition. The approach for derivation of each of these water quality model inputs are described in the sections below.

3.8.4.2 Mine Site Waste Rock Surfaces

Surface waste deposition is not modelled for the remaining Operations, Closure and Post-Closure periods (*i.e.,* 2021 onwards). However, the historic deposition continues to be incorporated in the water quality model, therefore the source term description is provided below for reference.

The N loading rate is estimated from: 1) the observed changes in the WRTSF total N inventory attributable to waste rock deposition, and 2) the tracked tonnages of waste rock deposited to the WRTSF for the 2016 through 2021 period. Surface excavation and WRTSF deposition was primarily conducted May 2015 through December 2016 during mine construction. There was no significant additional blasted surface waste placed in the WRTSF from 2017 through 2021. Waste rock from surface and underground excavation were deposited concurrently to the WRTSF, but at varying proportions over time; therefore, N load rates were derived for both surface and underground materials to fully account for the incremental change in the WRTSF N inventory between each monitoring event.

The WRTSF water quality data and total surface waste rock deposition are used to derive N loading rates for surface waste rock deposited to the WRTSF (Table 3-45). The total N loading rate of surface waste rock to the WRTSF is calculated to be 0.004 kg-N/t for the January 2016 to January 2017 monitoring period. For modelling, the surface waste rock loading rates were conservatively rounded up to 0.005 kg-N/t for the Base Case and 0.008 kg-N/t for the Upper Case.

Table 3-45:
N loading from surface waste rock to the WRTSF

Loading Term(g-N/t)	Base Case	Upper Case
Surface Waste	5	8

3.8.4.3 Mine Site Runoff

Core mine site surface facilities, including the mill, phase 2 camp, and VOK portal building (and their respective pads constructed by excavating PAG rock and placing NPAG fill), are located within the CWP catchment. Surface runoff from precipitation within the CWP catchment is accumulated in the CWP via the contact water management system (SRK, 2020), which includes ditches, manholes, piping and pumping systems to intercept and redirect runoff. The CWP is also used to store treated WTP effluent and any off-specification WTP effluent. The CWP is pumped to the WTP for treatment and mixes with other influent streams directed to the WTP (*i.e.*, process water and mine water).

The mine site runoff N source terms include N loading from surface blasting and from placement of NPAG Quarry fill used for the construction of pads and roads located within the CWP catchment. The N loading rates to mine site runoff are estimated to be 20% of the loading rates derived for surface waste deposited to the WRTSF, specifically 1 and 2 g-N/t for Base Case and Upper Case, respectively (Table 3-46). Loading rates were not measured during the 2015 through 2021 monitoring period therefore monitoring data are not available for comparison to model assumptions.

Table 3-46:
N loading to mine site runoff within the CWP catchment and to the WRTSF from NPAG quarry operations outside the CWP catchment

Loading Term	Base Case	Upper Case
	g-N/t	
Pit Wall contact water	1	2
Fill contact water	1	2

3.8.4.4 NPAG Quarry Pit and Road Fill Runoff

The NPAG Quarry is located near the southeast end of the WRTSF, with runoff from this area reporting directly to the WRTSF. Approximately 1,114 kt of rock was excavated from the NPAG Quarry from 2015 through 2021 (Table 3-2) to provide material for building foundations, roads, and other construction activities at the mine site. The excavated quarry rock is also crushed and placed in the underground mine as road surfacing. The projected NPAG Quarry rock excavation schedule is 50,000 t/yr for LOM. N species source terms were developed for drainage in contact with exposures in the NPAG Quarry as well as drainage from roads and pads constructed from NPAG Quarry rock.

The NPAG Quarry runoff includes N loading from the quarry pit walls and from the fill used for access roads outside the mine site area (*i.e.,* outside the CWP catchment). The N source terms for NPAG Quarry runoff are the same as the mine site runoff source terms presented above in Table 3-46. The Base Case and Upper Case loading rates are 1 and 2 g-N/t, respectively. The NPAG Quarry N loading rates have not been measured and therefore monitoring data are not available for comparison to model assumptions.

The N loads associated with NPAG Quarry rock placement within the mine site catchment are included with mine site runoff (see Section 3.8.4.3). NPAG Quarry rock is also used for road surfacing in the underground mine and N contributions from this placement are included in the of mine water N source terms (Section 3.8.5.2).

3.8.5 Underground Mine

3.8.5.1 Overview

As described in Section 2.1.3, the 4950 tpd mine plan will result in excavation of waste rock and ore through 2029. The waste deposition schedules are provided in Table 3-12 and Table 3-13; whereas the ore schedule is presented in Table 3-39.

In the underground mine, N is released to mine water from blasted rock, waste rock and paste backfill, and exposed mine surfaces (*i.e.,* walls). The N loading is modelled to be proportional to the quantity of rock blasted and the quantity of blasted rock placed as backfill. The loading of N from waste backfill to Mine Water is estimated to be 20% of the rate for waste to the WRTSF. Blasted ore is directed to the mill and the N loading rate for ore is described in Section 3.8.6.2. The derivation of the N loading rate for paste backfill is described in Section 3.8.6.3.

N source terms were developed for:

1) Underground mine waste rock deposited in the WRTSF; and,
2) Contact water from the underground mine.

3.8.5.2 Blasted Rock and Mine Water

As described in Section 3.4.3, the underground mine workings at the Brucejack Mine occur primarily below the groundwater table, and thus dewatering of the workings is required for all active phases of the mine. The N species arising from explosives used for blasting waste rock and ore are transferred to underground mine water through the dissolution of N species at the blast location, both through contact with groundwater that enters the mine and contact with mine water used for dust suppression. Backfilled waste and cement paste also contribute N to mine water; however, these contributions are accounted for separately in Section 3.8.5.4 (for waste) and Section 3.8.6.3 (for paste). The NPAG Quarry rock used for underground mine road surfacing contributes comparatively small loads to mine water; these loads are assumed to be captured in the derivation of the blasted rock N loading rate to mine water. Water supplied to the underground mine contributes to the mine water N concentrations and these contributions are derived within the water quality model.

Mine water N loading rates from blasted rock are calculated from water quality, flow and blasted rock tonnage records for the January 2015 through July 2017 period. These calculations yield N loading rates of 0.022 and 0.033 kg-N/t as source terms for the Base Case and Upper Case water quality model calculations (Lorax, 2018). The total N is distributed between ammonia, nitrite and nitrate based on the species distributions for N source terms presented in Section 3.8.7.

The observed N loading rates for a monthly time step during the June 2017 to August 2022 monitoring period are plotted in Figure 3-11. The cumulative N loading rate for the period is 29 g-N/t, near the mid-point between the Base and Upper Case assumptions (Table 3-47). The N loading rate for mine water was derived for the January 2015 through July 2017 monitoring period, during which time the dominant source of N to mine water was from blasting. Since July 2017 paste backfill has been placed in mined out stopes and water supplied to the underground mine has increased in both volume and N species concentrations. Waste rock is also backfilled into secondary stopes. These additional contributions are presumed to account for the 29 g-N/t loading rate to mine water that is observed for the 2017 to 2021 monitoring period compared to the Base Case loading rate derived from the 2015 to 2017 data. Therefore, the 2018 water quality model (Lorax, 2018) Base Case N load rate (22 g-N/t) is considered to best represent the N loads to mine water arising from blasting. The N loads from paste backfill bleed water and waste rock backfill are accounted for separately in section 3.8.5.4 and section 3.8.6.3.

Table 3-47:
N loading rates for underground ore, waste rock and paste backfill to Mine Water, the WRTSF and the Mill

Loading Term (g-N/t)	2015 – August 2022 Monitoring Period	Base Case	Upper Case
Blasted rock to Mine Water	29	22	33

Figure 3-11: Observed N loading from blasted rock to mine water from May 2017 through August 2022.

3.8.5.3 Mine Wall Surfaces

The mine wall source term accounts for N residues on mine walls and floors. Blasting generates N containing gases such as ammonia and nitrogen oxides that condense on exposed surfaces throughout the mine workings. During operations the mine is dewatered and N compounds (ammonia, nitrate and nitrite) accumulate on the exposed surfaces in the underground workings. The N loading rate for mine wall surfaces was derived from the wall wash monitoring program (described in the ML/ARD Management Plan) which measures water soluble residues on the mine walls and floors. The N residues are assumed to be released to contact water when the mine is flooding during closure. The N loading rates for wall and floor surfaces to mine water are 0.383 and 0.567 g-N/m^2, for the Base Case and Upper Case water quality model source terms (Table 3-48). The total N is distributed between ammonia, nitrite and nitrate based on the species distributions for N source terms presented in Section 3.8.7.

Table 3-48:
N loading rates for mine walls to mine water during mine flooding

Loading Term	Base Case	Upper Case
	(g-N/m^2)	(g-N/m^2)
Mine Walls to Mine Water	0.383	0.567

3.8.5.4 Waste Rock Surfaces

Most N residues from blasting remain on blasted waste rock surfaces. The residues can be released to contact water at the waste storage location. Excavated waste rock placed in the WRTSF is assumed to release all N residues to the WRTSF at the time of deposition. Waste placed as backfill in secondary stopes is assumed to release 20% of the N load to contact water from dust suppression or groundwater seepage at the time of deposition. During mine flooding, it is assumed that there will be limited flow through the waste rock pore water due to the confined placement of the rock. Therefore, waste backfill is assumed to release 10% of the N load to mine water during mine flooding.

The estimates of N loading rates to the WRTSF from waste rock are derived by mass balance of the WRTSF for total N accounting for inputs, storage and discharges of N species over a 2 year period. The water residence time the WRTSF is approximately 2 years, based on the WRTSF volume and BJ 3.10 discharge measurements for the 2015 through 2021 period. Therefore, a two-year period is considered appropriate for the derivation of the waste rock N loading rate to the WRTSF using a mass balance approach.

The change in the N inventory of the WRTSF plus the N loads exported from BJ 3.10 are corrected for the N loads added the WRTSF from the WTP effluent and tailings discharge.

The modelled N loading rates for underground waste to the WRTSF is shown in Table 3-49. These are derived from the average and maximum values of the waste rock N loadings for each two-year period from 2015 to 2021, and are 93 and 143 g-N/t for Base Case and Upper Case, respectively (Figure 3-12). The overall loading rate for the monitoring period (2015-2021) is 94 g-N/t.

For waste placed as underground backfill, it is assumed that a small proportion of the N load on the waste rock will be released to mine water and the remainder will remain sequestered in the backfilled stope. As shown in Table 3-49, the N loading rates for backfill at time of placement and during mine flooding are set at 19 and 29 g-N/t, and 14 and 17 g-N/t, Base Case and Upper Case, respectively. The total N loads are distributed between ammonia, nitrite and nitrate based on the distribution for N source terms presented in Table 3-52.

Table 3-49:
N loading rates for underground waste rock to WRTSF and mine water

Loading Term (g-N/t)	2015 – 2021 Monitoring Period	Base Case	Upper Case
Waste Rock to WRTSF	94	93	143
Waste Rock Backfill to Mine Water (at time of placement)	-	19	29
Waste Rock Backfill to Mine Water (during mine flooding)	-	14	17

Figure 3-12: Observed annual N loading from waste rock to the WRTSF.

3.8.6 Mill Components

3.8.6.1 Overview

Nitrogen enters the mill through ore, mine water and reclaim water from the WRTSF. The export of N from the mill occurs in backfill tailings paste, as well as discharges of WTP effluent to water supply and the WRTSF, and thickened tailings discharged to the WRTSF. The water quality model uses all the N source terms described in previous sections, as well as for ore (described below) to derive N species concentrations in the mill components of the GoldSim model as described in Section 3.6.1. The following sections describe N source terms developed for ore and the assumptions regarding the release of N loads from tailings and paste backfill.

3.8.6.2 Ore Surfaces

The N loads on ore surfaces are measured using milling records and monitoring data collected from the commencement of ore milling (June 2017). The production (ore) mining method uses the long-hole blasting technique rather than the short rounds used for mine development (waste) blasting, therefore the N loading rate for ore is expected to be lower than for waste.

The N loads on ore are derived from the 75th and 90th percentiles of weekly load measurements over the June 2017 to September 2017 period to yield N source terms of ore loading to the mill of 28 g-N/t and 54 g-N/t, respectively, for Base Case and Upper Case (Table 3-50). The ore N loading rate was measured weekly from June through October 2017, and monthly thereafter. The total N loads are distributed between ammonia, nitrite and nitrate based on the species distribution for N source terms presented in Table 3-52. The weekly N loading rate measurements are compiled as monthly average values for the June through October 2017 period and are used with other monthly measurements to calculate a median monthly N loading rate from ore for June 2017 though August 2022. The median ore N loading rate is 22 g-N/t of ore, well below the Base Case model assumption (28 g-N/t) as shown in Figure 3-13. The N loading rate is sometimes elevated compared to the Base Case with 75th and 95th percentile values of 31 and 45 g-N/t, respectively.

Table 3-50:
N loading rates for ore to the Mill

Loading Term (g-N/t)	2017 – 2022 Monitoring Period	Base Case	Upper Case
Blasted ore to mill	22 (median)	28	54

Figure 3-13: Observed N loading rate from ore to mill measured monthly from June 2017 through August 2022.

3.8.6.3 Tailings and Paste Backfill Loads

The water quality of the tailings supernatant discharged to the lake or placed underground as paste backfill are calculated by the GoldSim model based on N loads to the mill from mine water, ore and reclaim water. Base Case and Upper Case process water quality predictions are based on the Base Case and Upper Case terms for the components introduced to the mill.

Tailings discharged to the WRTSF are assumed to instantaneously release 100% of the N loads into the lake. In contrast, tailings placed underground as paste backfill are assumed to sequester more than 90% of the nitrogen compounds within the cured cemented paste. As described previously in Section 3.6.6, porewater contained in paste backfill that is not consumed during the cement curing process will be released as bleed water. Paste backfill bleed water monitoring data were used to estimate N loads transferred from the paste to the bleed water and N species distribution. Loading rates of 0.8 and 3 g-N/t, for Base Case and Upper Case, respectively, are derived from these data to model N release from paste to bleed water at the time of placement and at the time of mine flooding (Table 3-51). The bleed water volume is assumed to equal to approximately 2.5% of the water content in the paste.

Table 3-51:
N loading rates for Paste Backfill to Mine Water

Loading Term (g-N/t)	2017 – 2019 Monitoring Period	Base Case	Upper Case
Paste Backfill to Mine Water (at time of placement)	0.77 (median)	0.8	3
Paste Backfill to Mine Water (during mine flooding)	0.77 (median)	0.8	3

3.8.7 Nitrogen Speciation

Microbially-mediated nitrification processes occur naturally in cold water lakes and control the distribution of nitrogen species in the water column (Sterner, 2007), typically promoting an accumulation of nitrate. Brucejack Lake (now the WRTSF) is a cold water lake, and therefore the observations by Sterner (2007) are relevant to water quality modelling at Brucejack Mine. Nitrification rates in these environments are affected by temperature, nutrient levels, substrate and other environmental factors (Dvir & Neori, 1999; Kaplan *et al.*, 2000; Gerardi, 2002; Ward *et al.*, 2011; Bristow *et al.*, 2015) which may cause variations of the relative proportions of ammonia, nitrite and nitrate in the water column. Temporary decoupling of the rates of oxidation of N species by microbial communities can also occur, leading to temporary accumulation of ammonia or nitrite. The microbially-mediated oxidation of ammonia to nitrite is considered to be the rate-limiting step for overall nitrification (Ginestet *et al.,*1998). Active and inferred inhibited nitrification endpoints are used to model N species distributions in the WRTSF discharge.

The N species distributions in mine water, wall wash stations, the CWP and the WRTSF outlet (BJ 3.10) that were observed 2015 through 2021 were used to develop N speciation terms for modelling. The N loads are assigned the relative distributions indicated in Table 3-52 for the various N load sources. The N speciation for mine water is applied to the N source terms, except for mine wall residues during closure, and at the WRTSF outlet during operations and closure. The N loads at the WRTSF outlet (BJ 3.10) are redistributed as indicated in Table 3-52 to account for several possible nitrification endpoints.

Table 3-52:
Nitrogen (N) species relative distributions used for modelling

Model Term	Relative Distribution of N Species (% as N)		
	Ammonia	Nitrite	Nitrate
Mine water, ore to mill, waste to WRTSF and to backfill, paste backfill	28.8 %	5.2 %	66.0 %
Mine walls	46.5 %	3.2 %	50.3 %
WRTSF outlet (BJ 3.10)	23.2 %	0.84 %	99.9 %

The N species distributions at the WRTSF outlet are set conservatively for all N species. The species distributions are governed by conditions in the WRTSF water column. For the 2015 to 2022 monitoring period, the WRTSF conditions were oxidizing in the surface layer and mid-water column. Overall, the monitoring data at the WRTSF outlet continue to indicate nitrate accumulation and depletion of ammonia and nitrite relative to the inputs to the WRTSF. These changes are attributed to microbially mediated nitrification processes that convert ammonia to nitrite, and nitrite to nitrate (Sterner, 2007).

Data from the June 2017 through August 2022 monitoring period were used to derive N species relative distributions. The maximum ammonia value observed in the CWP water are used to represent a low nitrification endpoint (ammonia equal to 23.2% of N reporting to BJ 3.10), and maximum values from BJ 3.10 are used to model high nitrification endpoint (nitrate equal to 99.9 % of N reporting to BJ 3.10). The WRTSF monitoring data indicate that the proportion of nitrite remains low for both endpoints; therefore, the maximum ratio observed at BJ 3.10 (0.84 % of N reporting to BJ 3.10) was used for nitrite. Although the distributions sum to 124% of the total N predicted to report to BJ 3.10, this approach is considered appropriate as it addresses the uncertainty associated with continuity of the nitrification processes inferred to be active within the WRTSF.

4 Results

4.1 Overview

This section presents updated Brucejack Mine water quality model results for two monitoring sites: 1) BJ 3.10, the mine's regulated final discharge location at the outlet of the WRTSF; and 2) BJ 2.62, a downstream monitoring site in Brucejack Creek that will receive underground mine loads via groundwater pathways after the mine is flooded (Figure 1-1).

Water quality predictions for BJ 3.10 and BJ 2.62 are reviewed as compared to previous model predictions, to applicable discharge limits defined by PE-107835, or to BC FWAL guidelines. Parameters of potential concern (POPC) are identified through this assessment and predictions for these parameters are the focus of the results presented in the subsequent sections.

4.2 Identification of Parameters of Potential Concern

POPCs are identified as parameters predicted to have a base case concentration greater than 80% of a relevant threshold (ENV, 2019b). Parameters identified as POPCs require additional consideration to determine if there are reasons to exclude them from further assessment. Relevant thresholds for Brucejack Creek are discharge limits specified in PE-107835, or BC FWAL guidelines for parameters without discharge limits. There is no dilution zone associated with discharge from the WRTSF, since the discharge is the headwater of Brucejack Creek; therefore, PE-107835 discharge limits are relevant benchmarks for site BJ 2.62 and other locations in Brucejack Creek.

Screening of model results at BJ 3.10 and BJ 2.62 against discharge limits or FWAL guidelines generates the following list of POPCs that require additional review: ammonia, nitrite, nitrate, sulfate, aluminum, arsenic, copper, and selenium (Table 4-1 and Table 4-2). Parameters which are modelled to always have concentrations less than 80% of their discharge limit are not considered POPCs.

Table 4-1: Maximum concentrations from the BJ 3.10 Base Case water quality model, for all mine phases, compared to the maximum from previous model updates, BC water quality guidelines, PE-107835 effluent discharge limits, and POPC benchmarks.

Notes: 2020 water quality model presented in the 2020 Update (Lorax 2020a)
2018 water quality model presented in the 3800 tpd Permit Amendment Application (Lorax, 2018).
BC FWAL = BC water quality guidelines for protection of freshwater aquatic life.
POPC benchmark is equal to 80% of a discharge limit or 80% of a BC FWAL for parameters without discharge limits.
Bold font indicates parameters and concentrations that are greater than their POPC benchmark.
Concentrations that are higher in the current model than in both previous models are underlined.
Hardness dependent guidelines calculated using the baseline median hardness of 28 mg/L as $CaCO_3$.
Ammonia guidelines calculated using a pH of 8.0 and temperature of 15°C.
Copper guidelines calculated using the BC biotic ligand model. Inputs to the model were the 2019 annual averages measured at BJ 3.10 of pH 7.9, DOC 0.5 mg/L, Alkalinity 52 mg/L, Ca 24 mg/L, Mg 1.2 mg/L, Na 22 mg/L, K 7.7 mg/L, SO_4 46.5 mg/L, and Cl 1.6 mg/L. A summer temperature of 10 °C was used. The default of 10% of DOC present as humic acid was used.
Chromium guideline is for Cr(VI).
NP=none proposed.
NA=not applicable because the WQG is superseded by the discharge limit.

Table 4-2: Maximum concentrations from the BJ 2.62 Base Case water quality model, for all mine phases, compared to the maximum from previous model updates, BC water quality guidelines, PE-107835 effluent discharge limits, and POPC benchmarks.

4.3 Water Quality Predictions

This section presents the Base Case and Upper Case water quality predictions for parameters identified as POPCs (Section 4.2). Water quality predictions covering all mine phases are presented for both BJ 3.10 and BJ 2.62 alongside applicable water quality guidelines or discharge limits for reference. The BJ 3.10 predictions illustrate how the WRTSF responds to mine loadings received through LOM, whereas the downstream BJ 2.62 predictions illustrate how Brucejack Creek responds to loads from the WRTSF and the flooded underground mine via groundwater pathways during closure and post-closure.

For each monitoring site, water quality predictions are presented for two cases. The Base Case is considered to represent an expected case; whereas the Upper Case incorporates the combined loadings of upper case geochemical source terms for all inputs. The Upper Case source terms are generally based on 90th percentile values from geochemical or water quality monitoring datasets for all mine-related flows and employs highly conservative assumptions with respect to both contact water chemistry and onset of acidity. Tabulated results for all modelled parameters, for both cases are provided in Appendix A.

The water quality model predictions discussed in the following sections are presented as time series plots covering operations, closure and post-closure mine phases. The discussion of results focuses on observed trends related to the seasonal water balance, the geochemical behaviour of waste rock as a function of time (*e.g.*, the onset of ARD generation) and deposition schedules for the various inputs to the WRTSF (*e.g.*, waste rock, tailings, WTP effluent).

4.3.1 Ammonia

Ammonia originates primarily from blasting residues arising from explosives use. As described in Section 3.8, extensive investigations have been undertaken since 2015 to quantify nitrogen release from waste rock and tailings. The updated predictions for ammonia at both BJ 3.10 and BJ 2.62 are higher than previous model predictions (Table 4-1 and Table 4-2; Figure 4-1 and Figure 4-2); however, ammonia concentrations are not expected to exceed the discharge limit (4.0 mg/L) at any point through LOM.

Base Case ammonia concentrations at BJ 3.10 are predicted to increase through the first few years of operations under the 4950 tpd scenario as blasting activities in the mine increase, reaching a maximum concentration of 3.5 mg/L in 2025 (Figure 4-1). The concentrations of ammonia are predicted to decrease steadily after 2025 as the rate of blasting and explosive quantities decrease. This is reflected in the ammonia loading plot (Figure 4-3) which shows that waste rock loads, the dominant source of ammonia loads, decrease after 2025. Ammonia concentrations at BJ 3.10 continue to decrease at closure

both due to cessation of blasting and the fact that mine-related N loads will follow subsurface pathways to Brucejack Creek downstream of BJ 3.10. Ammonia concentrations are expected to return to background levels early in the post-closure phase.

Upper Case predictions of ammonia at BJ 3.10 follow the same trend as the Base Case predictions, with an increase in predicted concentrations early in operations, followed by a steady decrease for the remainder of operations and a return to background levels during post-closure.

Base Case and Upper Case ammonia predictions at BJ 2.62 show similar trends to predictions at BJ 3.10 during operations, but also have peaks during the closure phase. The closure peaks in ammonia concentrations (2.6 mg/L and 4.4 mg/L for Base Case and Upper Case, respectively) are attributed to flushing loads associated with flooding of the underground mine.

Figure 4-1: Base Case and Upper Case ammonia concentration predictions at BJ 3.10 through operations, closure and post-closure.

Figure 4-2: Base Case and Upper Case ammonia concentration predictions at BJ 2.62 through operations, closure and post-closure.

Figure 4-3: Sources of Base Case ammonia loadings to the WRTSF during operations.

4.3.2 Nitrite

As for other nitrogen species, nitrite originates primarily from blasting residues arising from explosives use. The updated predictions for nitrite at BJ 3.10 are lower than previous model predictions and are not expected to exceed the discharge limit (0.24 mg/L) at any point through LOM (Table 4-1 and Table 4-2; Figure 4-4 and Figure 4-5); however, nitrite concentrations at BJ 2.62 are predicted to be equivalent to the discharge limit for one month during closure.

Base Case nitrite concentrations at BJ 3.10 are predicted to increase through the first few years of operations under the 4950 tpd scenario as blasting activities in the mine increase, reaching a maximum concentration of 0.13 mg/L in 2025 (Figure 4-4). The concentrations of nitrite are predicted to decrease steadily through operations as the rate of blasting and explosive quantities decrease. The loading plot (Figure 4-6) illustrates this and shows that waste rock loads, the dominant source of nitrite loads, decrease through operations. Nitrite concentrations at BJ 3.10 continue to decrease at closure as blasting ceases and N loads from the mine are received by Brucejack Creek below BJ 3.10. Nitrite concentrations are expected to return to background levels early in the post-closure phase.

Upper Case predictions of nitrite at BJ 3.10 follow the same trend as the Base Case predictions, with an increase in predicted concentrations early in operations, followed by a steady decrease for the remainder of operations and a return to background levels during post-closure.

Base Case and Upper Case nitrite predictions at BJ 2.62 show similar trends to predictions at BJ 3.10 during operations, but have notable concentration peaks during the closure

phase. The closure peaks in nitrite concentrations (0.24 mg/L and 0.39 mg/L for Base Case and Upper Case, respectively) are attributed to flushing loads associated with flooding of the underground mine.

Figure 4-4: Base Case and Upper Case nitrite concentration predictions at BJ 3.10 through operations, closure and post-closure.

Figure 4-5: Base Case and Upper Case nitrite concentration predictions at BJ 2.62 through operations, closure and post-closure.

Figure 4-6: Sources of Base Case nitrite loadings to the WRTSF during operations.

4.3.3 Nitrate

Water quality predictions for nitrate at BJ 3.10 and BJ 2.62 are presented in Figure 4-7 and Figure 4-8, respectively. Concentrations of nitrate at BJ 3.10 for both Base Case and Upper Case scenarios are predicted to increase through the first few years of operations, as mining activities progress, reaching maximum concentrations in 2024 (15.2 mg/L and 24.7 mg/L for Base Case and Upper case, respectively). Base Case predictions are predicted to exceed the current discharge limit (11.5 mg/L).

The dominant source of nitrate loadings to the WRTSF are explosive residues associated with deposited waste rock and tailings (Figure 4-9). However, WTP effluent also contributes a significant load throughout operations.

After mining operations cease, nitrate concentrations at BJ 3.10 (both Base Case and Upper Case) decline steadily to background levels within the first few years of post-closure. Nitrate predictions at BJ 2.62 show a similar pattern to predictions at BJ 3.10, but with the marked peaks during closure due to the release of flushing loads as the mine is flooded (as described for ammonia in Section 4.3.1).

Figure 4-7: Base Case and Upper Case nitrate concentration predictions at BJ 3.10 through operations, closure and post-closure.

Figure 4-8: Base Case and Upper Case nitrate concentration predictions at BJ 2.62 through operations, closure and post-closure.

Figure 4-9: Sources of nitrate loadings to the WRTSF during operations.

4.3.4 Sulfate

Water quality predictions for sulfate at BJ 3.10 and BJ 2.62 are presented in Figure 4-10 and Figure 4-11, respectively. Sulfate concentrations within the WRTSF are predicted to gradually increase over operations with maximum concentrations at BJ 3.10 reached at the end of operations (113 mg/L and 297 mg/L, for Base Case and Upper Case, respectively). The observed increase in sulfate over the operations phase is primarily due to the expansion of the underground mine and corresponding increased annual loadings associated with tailings and WTP discharges to the WRTSF (Figure 4-12). Sulfate concentrations are predicted to decrease through closure, as ore processing, and discharge of tailings and WTP effluent cease.

Sulfate predictions for BJ 2.62 show the same pattern as observed at BJ 3.10 for operations, with maximum Base Case sulfate prediction of 104 mg/L. Increased concentrations are predicted for closure (up to 197 mg/L for the Base Case scenario) and are associated with the flushing loads released during flooding of the underground mine. Although the underground mine water will be treated through the flooding period and for 8 additional months, sulfate concentrations will not be mitigated since the WTP does not treat for sulfate. The flushing loads are expected to decrease over time and reach their long-term equilibrium concentration within the first few years of post-closure.

Figure 4-10: Base Case and Upper Case sulfate concentration predictions at BJ 3.10 through operations, closure and post-closure.

Figure 4-11: Base Case and Upper Case sulfate concentration predictions at BJ 2.62 through operations, closure and post-closure.

Figure 4-12: Sources of sulfate loadings (kg/month) to the WRTSF during operations.

4.3.5 Aluminum

Predicted concentrations of dissolved aluminum at BJ 3.10 and BJ 2.62 are presented in Figure 4-13 and Figure 4-14, respectively. Base case concentrations are predicted to go above BC FWAL guidelines during operations (maximum Base Case D-Al is 0.062 mg/L). Concentrations for both Base Case and Upper Case are predicted to increase early in operations and then decline towards the end of mine life. The dominant source of aluminum loadings is waste rock; however, the WRTSF also receives significant contributions seasonally from background (May to September) (Figure 4-15). The heavy waste deposited in the WRTSF also contributes a substantial D-Al load in 2023.

The BJ 3.10 predictions for D-Al continue to decline through the closure phase and reach long term post-closure concentrations within the first few years of post-closure. In contrast, D-Al predictions for BJ 2.62 increase during closure as flushing loads from the underground mine are received by Brucejack Creek. The Base Case predictions for BJ 2.62 show a slight increase, whereas the Upper Case predictions are more pronounced.

Figure 4-13: Base Case and Upper Case aluminum concentration predictions at BJ 3.10 through operations, closure and post-closure.

Figure 4-14: Base Case and Upper Case aluminum concentration predictions at BJ 2.62 through operations, closure and post-closure.

Figure 4-15: Sources of dissolved aluminum loadings (kg/month) to the WRTSF during operations.

4.3.6 Arsenic

Concentrations of total arsenic in the WRTSF are predicted to peak early in operations (Figure 4-16), with maximum Base Case and Upper Case predictions of 0.014 mg/L and 0.026 mg/L, respectively. A steady decline in concentrations of T-As at BJ 3.10 is predicted through the remainder of the operations phase, with concentrations reaching their long term equilibrated values early in post-closure. Predictions at BJ 2.62 (Figure 4-17) follow a similar pattern to concentrations at BJ 3.10 during operations, but increase during closure as mine-related loads are flushed and received by Brucejack Creek. The maximum Base Case T-As concentration predicted for BJ 2.62 is 0.012 mg/L during closure, slightly above the current discharge limit of 0.01 mg/L. Upper Case predictions are significantly higher (up to 0.027 mg/L) reflecting conservative assumptions for all loading terms.

Concentrations of T-As in the WRTSF (BJ 3.10) during operations are primarily influenced by the deposition of underground waste rock and, to a lesser extent, tailings discharges (Figure 4-18). Background levels of T-As are also relatively high and are expected to contribute seasonal loads throughout all mine phases.

The concentrations of T-As predicted for Brucejack Creek at BJ 2.62 during operations mirror predictions at BJ 3.10, but are slightly lower due to the contribution of additional background flows at the downstream station. At closure, loads from the flooded underground mine are received by Brucejack Creek via subsurface groundwater pathways, resulting in an increase in concentrations during closure and into post-closure.

Figure 4-16: Base Case and Upper Case total arsenic concentration predictions at BJ 3.10 through operations, closure and post-closure.

Figure 4-17: Base Case and Upper Case total arsenic concentration predictions at BJ 2.62 through operations, closure and post-closure.

Figure 4-18: Sources of total arsenic loadings to the WRTSF during operations.

4.3.7 Copper

BC updated its copper FWAL guidelines in 2019. The new guideline is applied to the dissolved Cu fraction and is calculated based on site water quality (hardness, pH, temperature, major ions, and dissolved organic carbon) using a biotic ligand model. The Cu guideline prior to August 2019 applied to total Cu and was calculated based on hardness of site water. For Brucejack Creek, which has low levels of hardness and DOC, the long-term (30-d average) FWAL guideline changed from T-Cu=0.002 mg/L to D-Cu= 0.0003 mg/L. The short-term (max) FWAL guideline changed from T-Cu= 0.0046 mg/L to D-Cu=0.0018 mg/L.

Concentrations of D-Cu at both BJ 3.10 (Figure 4-19) and BJ 2.62 (Figure 4-20) are predicted to go above the long-term FWAL guideline early in operations. The main source of Cu loadings to the WRTSF are waste rock and background, with contributions from WTP effluent and tailings increasing as operations progress (Figure 4-21). The annual maximum concentrations at BJ 3.10 peak at the end of operations (0.00042 mg/L and 0.0087 mg/L, for Base Case and Upper Case respectively).

In contrast, the maximum concentrations predicted for BJ 2.62 occur during closure, reaching maximum predicted concentrations of 0.00171 mg/L and 0.011 mg/L, for Base Case and Upper Case. The Base Case BJ 2.62 D-Cu predictions at closure are predicted to remain below the short-term FWAL guideline of 0.0018 mg/L, but seasonally go above the long-term guideline of 0.003 mg/L. The Upper Case D-Cu concentrations are predicted to go above the short-term guideline throughout closure and post-closure on a seasonal basis.

Figure 4-19: Base Case and Upper Case dissolved copper concentration predictions at BJ 3.10 through operations, closure and post-closure.

Figure 4-20: Base Case and Upper Case dissolved copper concentration predictions at BJ 2.62 through operations, closure and post-closure.

Figure 4-21: Sources of dissolved copper loadings to the WRTSF during operations.

4.3.8 Selenium

Water quality predictions for T-Se at BJ 3.10 (Figure 4-22) show an increasing trend through most of operations, reaching a maximum Base Case concentration of 0.0021 mg/L in 2027. The main source of Se loadings at the beginning of operations is waste rock, but as mining progresses, the contributions from tailings and WTP effluent become more significant (Figure 4-24). A decrease in concentrations is predicted for closure, with T-Se concentrations at BJ 3.10 reaching long term equilibrium levels within approximately 5 years of post-closure. The Base Case T-Se predictions at BJ 3.10 are predicted to go slightly above the BC FWAL guideline of 0.002 mg/L seasonally, starting in 2026. Upper Case predictions follow a similar trend to the Base Case predictions, but are significantly higher with concentrations predicted to go up to 0.0062 mg/L.

T-Se predictions at BJ 2.62 show the same pattern as for BJ 3.10 during operations, but reach maximum concentrations during the closure phase (Figure 4-23). The maximum predicted Base Case concentration of T-Se is 0.0037 mg/L. The elevated T-Se concentrations are predicted to occur on a seasonal basis during low flow months and decrease to long term equilibrium levels within approximately 5 years of post-closure.

Figure 4-22: Base Case and Upper Case total selenium concentration predictions at BJ 3.10 through operations, closure and post-closure.

Figure 4-23: Base Case and Upper Case total selenium concentration predictions at BJ 2.62 through operations, closure and post-closure.

Figure 4-24: Sources of total selenium loadings to the WRTSF during operations.

5 Aquatic Effects Assessment

5.1 Introduction

This section provides an assessment of potential effects from modelled water quality in Brucejack Creek to potential receptors (Figure 5-1). Aquatic life is the most sensitive receptor to changes in water quality. This is indicated by BC water quality guidelines, which are lower for aquatic life than for wildlife. As well, wildlife will infrequently use Brucejack Creek for drinking water, while aquatic life are continually exposed to Brucejack Creek water quality. Therefore, potential effects of water quality to wildlife are not assessed in this section. Potential effects to human health are discussed in Section 5.14.

Parameters of potential concern were identified in Section 4.2 as having a maximum Base Case model result at either BJ 3.10 (WRTSF effluent) or BJ 2.62 (receiving environment during closure and post-closure) that is greater than 80% of relevant benchmarks, either effluent permit discharge limits or BC FWAL guidelines for parameters that do not have discharge limits. POPCs identified are ammonia, nitrate, nitrite, sulfate, D-Al, T-As, D-Cu and T-Se.

Figure 5-1: Conceptual site model of contaminant transport to receptors.

5.2 Methods For Assessing Risk to Aquatic Life

Potential residual effects of predicted water quality on the aquatic community in Brucejack Creek are assessed using the following criteria:

- **Ecological Context**: the ecological setting in the receiving environment. Ecological context is categorized as **high** for receiving environment that includes sensitive habitats or habitats that have little resilience to changes in water quality or species that are red or blue listed by the B.C. Conservation Data Center; **medium** for habitat that includes fish or fish habitat; and **low** for habitats that do not include fish or fish habitat.
- **Geographic Extent**: the spatial scale over which concentrations of POCs are expected to be greater than environmental benchmarks (discharge limits or BC FWAL guidelines). The extent is categorized as **local** if concentrations of POCs are above benchmarks only in Brucejack Creek and **regional** if effluent discharge elevates concentrations above benchmarks in Sulphurets Creek.
- **Magnitude**: the potential severity for POCs to cause toxicity to aquatic life. The magnitude is categorized as **low** if modelled concentrations are less than half of a toxicity benchmark, **medium** if between 0.5 and 1 times a toxicity benchmark, and **high** if greater than a toxicity benchmark.
- **Duration**: the length of time that a POC is modelled to be greater than an environmental benchmark. Duration is categorized as **short-term** if modelled concentrations are elevated above its benchmark for 1 month of the year, **medium-term** if elevated for several months a year, **long-term** if elevated for more than a year, and **permanent** if post-closure concentrations are above a benchmark. Duration is categorized as **none** if modelled concentrations do not go above its environmental benchmark during the life of mine.
- **Frequency**: how often the effect occurs. Frequency is categorized as **single event**, **occasional** (concentrations are above benchmarks more than once, but irregularly), **regular** (seasonally elevated above benchmarks), or **continuous** (concentrations are above benchmarks throughout the year). Frequency is categorized as **none** if modelled concentrations do not go above its environmental benchmark during the life of mine.
- **Reversibility**: whether the effect to water quality can be reversed after mine operation ends. Effect to water quality is **reversible** if concentrations decrease below an environmental benchmark during post-closure and **irreversible** if concentrations above the benchmark occur more than five years into post-closure.

- **Resiliency**: the capacity of the aquatic community to recover from major changes in structure after mine operation ends. Resiliency is categorized as **high** if the aquatic community is expected to return to its pre-impact state within a few years of post-closure, **medium** if the aquatic community is expected to return to its per-impact state within a decade of post-closure, and **low** if recovery is expected to take more than a decade.
- **Consequence**: consideration of ecological context, geographic extent, magnitude, duration, frequency, reversibility, and resiliency are used to determine consequence of potential residual effects. Consequence is categorized according to the levels in Table 5-1, as described in ENV (2014).

Table 5-1:
Definitions of consequence ratings used in the residual impact assessment.

Consequence	Environmental Impact
Level 1	Limited damage to minimal area of low significance
Level 2	Minor effects on biological or physical environment
Level 3	Moderate short-term effects but affecting ecosystem
Level 4	Serious medium-term environmental effects
Level 5	Very serious long-term environmental effects

- **Likelihood**: the likelihood that adverse impacts will occur. Likelihood is categorized according to the definitions in Table 5-2, as modified from ENV (2014).

Table 5-2:
Definitions of likelihood ratings used in the residual impact assessment.

Description	Frequency of Environmental Impacts
Adverse effects are very likely	More than 1 event per month
Adverse effects are likely	More than 1 event per year
Adverse effects are unlikely	1 event per 1 to 10 years
Adverse effects are very unlikely	1 event per 10 to 100 years

- **Risk**: the risk of the project causing adverse effects is categorized based on the consequence of the effect and the likelihood of the effect, according to the matrix shown in Figure 5-2, as modified from ENV (2014).

		Consequence Severity				
		Level 1	**Level 2**	**Level 3**	**Level 4**	**Level 5**
Likelihood	**Very likely**	Moderate	High	Extreme	Extreme	Extreme
	Likely	Low	Moderate	High	Extreme	Extreme
	Unlikely	Low	Low	Moderate	High	Extreme
	Very unlikely	Low	Low	Low	Moderate	High

Figure 5-2: Categorization matrix for determining risk of adverse effects from modelled water quality to aquatic life in Brucejack Creek.

- **Confidence**: the confidence that the risk assessment is accurate. **Low** confidence is assigned to a risk rating with large data gaps, **moderate** is assigned to a risk assessment with some data gaps, and **high** is assigned to a risk assessement based on strong data to support the asssessment.

5.3 Ecological Context

Brucejack Creek and most of Sulphurets Creek are non-fish-bearing streams (Rescan, 2013a). In Sulphurets Creek, the upper limit of fish distribution is defined by a fish barrier approximately 1.3 km upstream of the Unuk River confluence (Figure 5-3). Therefore, fish-bearing waters are approximately 20 km downstream of Brucejack Creek and 23 km downstream of the outlet of the WRTSF. Invertebrates growing in Brucejack Creek will not be a food supply for fish at the mouth of Sulphurets Creek, given the long distance between Brucejack Creek and fish-bearing waters, as well as the presence of Sulphurets Lake which would trap detritus that drifts into upper Sulphurets Creek. Therefore, Brucejack Creek is non-fish bearing and is not fish habitat. No amphibians have been noted during ecological surveys of these streams (ERM, 2022a). Aquatic life in Brucejack Creek is limited to benthic invertebrates and periphyton.

PROJECT #: A624-4

FIGURE: 5-3

P:\@Drafting\Brucejack\Drafting Figures\MXD\2022 WQ Infrastructure\Receiving Environment Monitoring Sites_F5-1.mxd

Baseline biological surveys of Brucejack Creek in 2014 and 2015, and annual surveys during construction and operation of the mine, show that the assemblage of benthic invertebrate communities in Brucejack Creek is composed predominantly of chironomids (midges). Annelids (oligochaete worms) and Plecoptera (stoneflies) also comprise a significant proportion of the invertebrate community composition, with an apparent increase in the proportion of stoneflies since baseline (Figure 5-4). Other taxa were uncommon in Brucejack Creek. The community composition in Brucejack Creek has been different than at the reference stream (Lake L3 outfall) which has been predominantly stoneflies and mayflies (Ephemeroptera) with large proportion of chironomids observed only in 2020.

Notes: Ostracoda, Cladocera, Copepoda, Porifera, Nematoda, Platyhelminthes, fish and terrestrial invertebrates were excluded from all calculations. Immature, damaged and unidentified individuals were excluded from all analyses except abundance calculations. Figure is copied from Figure 5.4-2 of the 2021 Aquatic Resources Monitoring Report (ERM, 2022b).

Figure 5-4: Benthic invertebrate community composition by major taxon for Brucejack Creek, upper Sulphurets Creek, & reference lake L3 outfall.

None of the benthic invertebrate taxa collected from Brucejack Creek sites that were listed in the appendices of the annual Aquatic Resources Monitoring Reports and identified to genus level are present on the B.C. Conservation Data Center list of Red (endangered or threatened) or Blue (special concern) listed species.

There have been large interannual differences in total invertebrate abundance at the three sites sampled in Brucejack Creek (Figure 5-5). The total invertebrate abundance at site SC0 in Sulphurets Creek just downstream of Brucejack Creek has been markedly lower than the abundance in Brucejack Creek.

Notes: Ostracoda, Cladocera, Copepoda, Porifera, Nematoda, Platyhelminthes, fish and terrestrial invertebrates were excluded from all calculations. Figure is copied from Figure 5.4-1 of the 2021 Aquatic Resources Monitoring Report (ERM, 2022b).

Figure 5-5: Benthic invertebrate abundance at Brucejack Creek sites, upper Sulphurets Creek, & reference lake L3 outfall. Each bar represents the total number of identifiable individuals captured in a three-minute CABIN kick net (400 µm) survey.

Periphyton surveys in Brucejack Creek have found algal slimes on rocks composed of chlorophytes and diatom species. Macroalgae were not present.

Based on the biological monitoring data for Brucejack Creek and upper Sulphurets Creek that show these streams are non-fish-bearing, are not fish habitat, do not provide habitat for species that are endangered, threatened or of special concern, the ecological context of the receiving environment is considered **low**.

5.4 Resiliency

The aquatic ecosystem of Brucejack Creek is limited to benthic invertebrates and periphyton. If these taxa were adversely affected by discharge of mine effluent, they have the ability to recolonize streams through drift, upstream migration within the water, migration from within the substrate, and aerial sources (Williams and Hynes, 1976). Similarly, the periphyton that inhabit Brucejack Creek would be able to recolonize following a disturbance through resting spores present in sediment and through drift from upstream sources. A disturbance to the Brucejack Creek ecosystem by changes to water quality would not affect source populations for recolonization from nearby tributaries and streams, nor would the physical structure of the stream be altered by changes to water quality. Dispersal of invertebrates from upstream sources to disturbed streams has been shown to occur rapidly (days) (Baumgartner and Robinson, 2017) and seasonally from aerial sources (Westveer *et al.,* 2018). The ability of taxa that are present in Brucejack Creek to rapidly colonize streams after a disturbance indicates that the resiliency of the ecosystem is **high**.

5.5 Geographic Extent

The discharge from the WRTSF is the headwaters of Brucejack Creek. There is little dilution that occurs over the 3 km length of Brucejack Creek. During operations, when all mine loadings are directed to the WRTSF, it is assumed that the concentration modelled for BJ 3.10 is representative of all of Brucejack Creek. During closure and post-closure, mine related loadings from the WRTSF are relatively low since most loadings are derived from the underground mine pool. The water quality model has most of the loadings from the flooded underground mine reporting via subsurface pathways to BJ 2.62; therefore, the concentrations modelled for BJ 2.62 are considered representative of concentrations throughout Brucejack Creek.

Brucejack Creek flows under the Sulphurets Glacier into Sulphurets Lake at the headwaters of Sulphurets Creek (Table 5-3; Figure 5-3). The monthly mixing ratio of flow at the outlet of Sulphurets Lake (site SL-H2) with flow from BJ 3.10 varies seasonally from a minimum of 6:1 in December to a maximum of 21:1 in August (Table 5-3). There are considerably higher monthly mixing ratios that occur farther downstream, just upstream of Mitchell Creek (site SC-MCU).

Table 5-3:
Monthly streamflow ratios at nodes along the Sulphurets Valley

Month	BJ 3.10	SL-H2	SC-MCU
Jan	1	8	25
Feb	1	9	25
Mar	1	9	25
Apr	1	8	25
May	1	8	16
Jun	1	9	17
Jul	1	19	34
Aug	1	21	37
Sep	1	18	32
Oct	1	15	28
Nov	1	9	19
Dec	1	6	17

Notes: Data are reproduced from Table 5 of ERM (2017) which is included as Appendix B of this report.
Node SL-H2 is Sulphurets Creek at Sulphurets Lake Outlet.
Node SC-MCU is Sulphurets Creek just upstream of Mitchell Creek.

The geographic extent of changes to water quality is categorized as local if the modelled concentrations in Brucejack Creek cannot elevate the concentration in upper Sulphurets Creek to a level that is greater than the BC FWAL long-term guideline. If there is the potential that the modelled concentration in Brucejack Creek will elevate the concentration in upper Sulphurets Creek to greater than the BC FWAL guideline, then the geographic extent of changes to water quality is categorized as regional.

The final concentration in upper Sulphurets Creek is conservatively assessed by assuming that the maximum modelled concentration at BJ 3.10 or BJ 2.62 will coincide with the minimum mixing ratio of 6:1 in upper Sulphurets Creek. The concentration at site SC0, in Sulphurets Creek just upstream of Sulphurets Lake is calculated using the following mass balance equation:

$$C_f = \frac{C_1 V_1 + C_2 V_2}{V_1 + V_2}$$

where: C_1 = concentration at BJ 3.10 or BJ 2.62
C_2 = background concentration in upper Sulphurets Creek
C_f = final concentration at SC0
V_1 = flow at BJ 3.10 (set to 1)
V_2 = flow at SC0 (set to 6)

The background concentrations (C_2) used in these calculations are the median concentrations from baseline sampling (2011-2013) at site SC0, during shifted quarter four (sQ4) (Nov.-Jan.) which coincides with the period of minimum mixing ratio. The mass balance equation can be rearranged to solve for C_1 (concentration at BJ 3.10) that would

be required to create a concentration at SC0 that is equal to BC FWAL guidelines when the mixing ratio is 6:1.

5.6 Ammonia

Ammonia was identified as a POPC because the maximum Base Case modelled concentration at BJ 3.10 (3.53 mg-N/L) is greater than 80% of the discharge limit (4 mg-N/L). Measurements of ammonia concentrations at BJ 3.10 show that the Base Case model overestimates the levels of ammonia that are discharged from the WRTSF (Figure 5-6). This is likely due to ammonia being oxidized to nitrate in the WRTSF at a rate that the mass balance model does not account for. Since the Base Case model results are less than the discharge limit, and the Base Case model overestimates measured concentrations at BJ 3.10, ammonia is not considered a POC and no further assessment related to effects on aquatic life in Brucejack Creek has been carried out for ammonia.

Figure 5-6: Base Case modelled ammonia concentrations at BJ 3.10 (top) and BJ 2.62 (bottom) compared to the PE-107835 discharge limit and to measured concentrations.

5.7 Nitrate

5.7.1 Introduction

Nitrate levels in Brucejack Creek have increased since mine operations began in 2017, in agreement with the Base Case model (Figure 5-7). The maximum modelled nitrate

concentration during any of the mine phases is 15.2 mg-N/L for the Base Case model and 24.7 mg-N/L for the Upper Case model. These modelled concentrations are higher than the current discharge limit in PE-107835 of 11.5 mg-N/L. The discharge limit was established in 2016 based on the maximum Upper Case model result at that time, which was based on a mine production rate of 2700 tpd. A higher rate of explosive use for the 4950 tpd mine is the primary reason that modelled nitrate concentrations in Brucejack Creek are higher than the discharge limit set based on modelling done for the 2700 tpd production rate.

Figure 5-7: Modelled nitrate concentrations at BJ 3.10 (top) and BJ 2.62 (bottom) compared to the PE-107835 discharge limit and to measured concentrations.

5.7.2 Geographic Extent

The geographic extent of effects to nitrate concentrations is assessed by estimating if concentrations in upper Sulphurets Creek, at SC0, have the potential to become elevated above the long-term WQG (3 mg-N/L). This is done using a mass balance equation and a minimum mixing ratio of 6:1 (parts SC0 to parts Brucejack Creek water) (see section 5.5).

The background concentration used in the mass balance model is set to the median nitrate concentration for sQ4 (0.03 mg-N/L). More recent monitoring at SC0 indicates that nitrate levels have been influenced by discharge from the WRTSF, but are well below the BC FWAL guideline (Figure 5-8).

Figure 5-8: Nitrate concentrations in upper Sulphurets Creek measured quarterly since baseline.

During operations, the maximum Base Case modelled concentration is 15.2 mg-N/L, and the maximum Upper Case modelled concentration is 24.7 mg-N/L. The Base Case does not have the potential to cause nitrate levels at SC0 to increase to above the BC long-term FWAL guideline, but the Upper Case does (Table 5-4). Therefore, during operations, the geographic extent of changes to nitrate concentrations is **local** for the Base Case and **regional** for the Upper Case.

Modelled concentrations of nitrate are lower during closure and post-closure because explosives are not used during these mine phases. The lower concentrations of nitrate during closure and post-closure result in the geographic extent of changes to nitrate concentration being **local**, for both the Base Case and Upper Case (Table 5-4).

Table 5-4:
Final nitrate concentration in upper Sulphurets Creek for maximum modelled concentrations in Brucejack Creek during different mine phases.

Mine Phase	Model	C_1 (mg-N/L)	C_2 (mg-N/L)	V_2	V_1	C_f (mg-N/L)
Operations	Base Case	15.2	0.03	6	1	2.2
Operations	Upper Case	24.7	0.03	6	1	**3.6**
Closure	Base Case	8.9	0.03	6	1	1.3
Closure	Upper Case	15.3	0.03	6	1	2.2
Post-closure	Base Case	0.2	0.03	6	1	0.05
Post-closure	Upper Case	0.3	0.03	6	1	0.06
	Maintain SC0 under the FWAL guideline	20.1	0.03	6	1	2.9

Notes: C_1 = source concentration at BJ 3.10 or BJ 2.62
C_2 = background concentration in upper Sulphurets Creek
C_f = final concentration at SC0
V_1 = flow at BJ 3.10 or BJ 2.62 (set to 1)
V_2 = flow at SC0 (set to 6).

Solving the mass balance equation for C_1 when the final concentration at SC0 is set to 2.9 mg-N/L (just below the BC FWAL guideline) shows that a discharge of up to 20 mg-N/L at BJ 3.10 will not cause the concentration at SC0 to increase above the BC FWAL guideline.

5.7.1 Magnitude

Potential adverse effects of elevated nitrate levels to aquatic life in Brucejack Creek are through eutrophication or toxicity.

5.7.1.1 Eutrophication

Eutrophication is the process by which lakes and streams become biologically more productive due to increased supply of nutrients (phosphorus and/or nitrogen) (MECCS, 2021). In the overwhelming majority of cases, phosphorus is the limiting nutrient (MECCS, 2021). The nitrogen concentration is only rarely of concern since it does not limit algal growth except in very unusual circumstances (MECCS, 2021).

Phosphorous levels modelled for the 4950 tpd mine plan are not higher than were modelled for the 3800 tpd mine plan (Table 4-1). This indicates that phosphorus will continue to be the nutrient that limits periphyton growth in Brucejack Creek, and increasing concentrations of nitrogen compounds (nitrate, nitrite, and ammonia) in Brucejack Creek will not change its trophic status. Annual measurements of periphyton biomass, measured as the concentration of chlorophyll *a* per square meter, at sites in Brucejack Creek have been low compared to the BC FWAL guideline of 100 mg/m^2 (10 $\mu g/m^2$), and have not had a noticeable change over time (Figure 5-9). The lack of change in periphyton biomass over time, even though nitrate levels have increased (Figure 5-7) is expected because there has not been in increase in the supply of biologically available phosphorus, which has been below its detection limit in most samples from BJ 3.10 (Figure 5-10). Because no changes to periphyton biomass are expected to result from changes in water quality in Brucejack Creek associated with the 4950 tpd, the magnitude of potential changes to trophic status of the Brucejack Creek ecosystem is considered **low**.

Notes: Figure is copied from Figure 5.3-1 of the 2021 Aquatic Resources Monitoring Report (ERM, 2022b).

Figure 5-9: Periphyton biomass measured annually at sites in Brucejack Creek, upper Sulphurets Creek, and reference site L3 OF measured annually since baseline.

Figure 5-10: Dissolved ortho-phosphate concentration measured weekly at BJ 3.10.

5.7.1.2 Toxicity

The potential for nitrate to be toxic to aquatic life in Brucejack Creek was assessed using site-specific toxicity testing. Nitrate bioassays were conducted by Nautilus Environmental by spiking water collected from BJ 3.10 on December 7, 2021 with various concentrations of nitrate and measuring the effect on species that are representative of aquatic life in Brucejack Creek (Appendix C). Nitrate bioassays were conducted using the waterflea *Ceriodaphnia dubia* and the chironomid *Chironomus dilutus*. *Ceriodaphnia dubia* is an invertebrate that has been shown to be sensitive to chronic toxicity from nitrate (CCME, 2012). *Chironomus dilutus* is representative chironomids, which are the most common invertebrate taxa in Brucejack Creek. Bioassays using algae were not conducted because nitrate is a macronutrient for periphyton, and algae are known to grow well in high concentrations of nitrate.

Chironomus dilutus was more sensitive to acute toxicity than *C. dubia*, but less sensitive to chronic toxicity than *C. dubia* (Table 5-5). The lowest toxicity endpoint in the site-specific bioassays of nitrate was an IC20 of 54.1 mg-N/L. This is the concentration that caused a 20% reduction in growth (measured as dry weight) over the 10-day bioassay.

Table 5-5:
Results of toxicity testing of nitrate in BJ 3.10 water.

Endpoint	Units	*C. dubia*	*C. dilutus*
Survival LC50	mg-N/L	>303	150.7
Growth or Reproduction IC20	mg-N/L	54.1	179.6
Growth or Reproduction IC50	mg-N/L	88.5	>303

The maximum Base Case model result for nitrate in Brucejack Creek, during all mine phases, is 15.2 mg-N/L. This concentration is 3.6 times lower that the lowest chronic endpoint in the site specific bioassays; therefore, the magnitude of potential toxicity effects to aquatic life in Brucejack Creek is considered **low** for all Base Case model results.

The maximum Upper Case model result for nitrate in Brucejack Creek, during all mine phases, is 24.7 mg-N/L. This concentration is 2.2 times lower that the lowest chronic endpoint in the site specific bioassays; therefore, the magnitude of potential toxicity effects to aquatic life in Brucejack Creek is considered **low** for all Upper Case model results.

5.7.2 Duration, Frequency, and Reversibility

Base Case and Upper Case modelled concentrations of nitrate are above the discharge limit for much of the operations phase, then decrease after the use of explosives ceases, at the

end of operations (Figure 5-7); therefore, the duration of elevated nitrate concentrations is **long-term** for both the Base Case and Upper Case.

The Base Case and Upper Case results are above the discharge limit during low flow months, and below the discharge limit during high flow months. Since nitrate is modelled to seasonally exceed its discharge limit, the frequency of elevated nitrate concentrations is **regular**, for both the Base Case and Upper Case.

The Base Case and Upper Case results return to concentrations near baseline levels during post-closure; therefore, the effects of mining on nitrate levels are **reversible**, for both the Base Case and Upper Case.

5.7.3 Consequence

Eutrophication due to Base Case modelled concentrations of nitrate in Brucejack Creek is not expected (**Level 1**). Toxicity to aquatic life in Brucejack Creek from Base Case modelled nitrate levels is not expected, since the maximum modelled concentration is 3.5 times lower than the lowest chronic toxicity endpoint and 10 times lower than the lowest acute toxicity endpoint (Table 5-5). Since the ecological context of Brucejack Creek is low, and no toxicity to aquatic life in Brucejack Creek is expected, the potential consequence of the Base Case modelled nitrate concentrations is low (**Level 1**).

Eutrophication due to Upper Case modelled concentrations of nitrate in Brucejack Creek is not expected (**Level 1**). Toxicity to aquatic life in Brucejack Creek from Upper Case modelled nitrate levels is not expected since the maximum modelled concentration is 2.0 times lower than the lowest chronic toxicity endpoint and 5.5 times lower than the lowest acute toxicity endpoint (Table 5-5). Since the ecological context of Brucejack Creek is low, and no toxicity to aquatic life in Brucejack Creek is expected, the potential consequence of the Base Case modelled nitrate concentrations is low (**Level 1**).

5.7.4 Likelihood

To date, nitrate concentrations at BJ 3.10 have been well represented by the Base Case model and overestimated by the Upper Case model (Figure 5-7). Eutrophication resulting from Base Case and Upper Case modelled concentrations is **very unlikely**, since periphyton growth is limited by phosphorous, and phosphorous concentrations are expected to remain very low.

Base Case modelled concentrations are likely to occur, but toxicity to aquatic life in Brucejack Creek from Base Case concentrations is **very unlikely**. Toxicity from the Upper Case modelled concentrations is unlikely, which, combined with the expectation that Upper Case nitrate concentrations are very unlikely to occur, indicates that adverse effects to aquatic life from Upper Case modelled concentrations is **very unlikely**.

5.7.5 Risk

Both Base Case and Upper Case model results have a Level 1 consequence and are very unlikely to cause eutrophication or toxicity; therefore, the risk of adverse effects from modelled nitrate levels is **low**, for both the Base Case and Upper Case (Figure 5-2).

5.7.6 Confidence

The comparison of modelled nitrate concentrations to five years of monitoring data provides high confidence that the Base Case model well represents expected nitrate concentrations for the 4950 tpd mine plan, and that the Upper Case model overestimates nitrate levels in Brucejack Creek. Monitoring of periphyton biomass from baseline through 2021 has shown that the increase in nitrate concentrations that have occurred since mine construction have not resulted in eutrophication, which provides high confidence that a further increase in nitrate levels due to the 4950 tpd mine plan will not result in eutrophication. The site-specific toxicity testing that was done provides a direct measure of toxicity to species that are representative of aquatic life in Brucejack Creek, which provides a high level of confidence in the assessment of potential toxicity from nitrate. Overall, there is **high** confidence in the assessment of potential risk to aquatic life from the modelled nitrate concentrations.

5.7.7 Summary

The risk of eutrophication from Base Case and Upper Case modelled nitrate concentrations is categorized as low for all mine phases (Table 5-6). The risk of toxicity from Base Case and Upper Case modelled nitrate concentrations is categorized as low for all mine phases (Table 5-7).

5.8 Nitrite

5.8.1 Introduction

Nitrite concentrations in Brucejack Creek are modelled to remain below the PE-107835 discharge limit during operations, for both the Base Case and Upper Case models (Figure 5-11). Comparison of measured and modelled concentrations of nitrite in Brucejack Creek show that the model generally overestimates nitrite levels, although concentrations increased in November and December 2021 to levels that approached Base Case modelled concentrations (Figure 5-11). Modelled nitrite levels at BJ 3.10 decrease toward the end of operations, due to lower rates of explosive use.

Figure 5-11: Modelled nitrite concentrations at BJ 3.10 (top) and BJ 2.62 (bottom) compared to the PE-107835 discharge limit and to measured concentrations.

Base Case modelled nitrite concentrations at BJ 2.62 peak during closure to equal the the discharge limit of 0.24 mg-N/L, and Upper Case peaks are above the discharge limit for two seasons, in response to the flushing water from the flooded underground mine that reports to Brucejack Creek. Modelled concentrations at BJ 2.62 decrease each year during closure and are below the discharge limit during post-closure, for both the Base Case and Upper Case models.

5.8.2 Geographic Extent

The geographic extent of effects to nitrite concentrations is assessed by estimating if concentrations in upper Sulphurets Creek, at SC0, have the potential to become elevated above the long-term WQG (0.02 mg-N/L). This is done using a mass balance equation and a minimum mixing ratio of 6:1 (parts SC0 to parts Brucejack Creek water) (see section 5.5).

The background concentration used in the mass balance model is set to the median baseline concentration for sQ4 (0.0005 mg-N/L). More recent monitoring at SC0 indicates that nitrite levels may have been influenced by discharge from the WRTSF, but are well below the BC FWAL guideline (Figure 5-12).

Figure 5-12: Nitrite concentrations in upper Sulphurets Creek measured quarterly since baseline.

The maximum modelled nitrite concentration during operations phase is 0.13 mg-N/L for the Base Case and 0.21 mg-N/L for the Upper Case (Table 5-8). The Base Case nitrite concentrations during operations do not cause concentrations at SC0 to increase above the BC FWAL guideline (Table 5-8); therefore, the geographic extent of potential effects to water quality is **local** during operations for the Base Case. Upper Case predictions during operations, and both Base Case and Upper Case predictions during closure, result in periods when dilution will not bring nitrite concentrations in upper Sulphurets Creek to less than the BC FWAL guideline; therefore, the geographic extent of changes to nitrite concentration is **regional** for these model conditions. During post-closure, nitrite levels in Brucejack Creek are low and the geographic extent of changes to water quality is **local**.

Table 5-8:
Final nitrite conentration in upper Sulphurets Creek for maximum modelled concentrations in Brucejack Creek during different mine phases.

Mine Phase	Model	C_1 (mg-N/L)	C_2 (mg-N/L)	V_2	V_1	C_f (mg-N/L)
Operations	Base Case	0.128	0.0005	6	1	0.019
Operations	Upper Case	0.208	0.0005	6	1	**0.030**
Closure	Base Case	0.244	0.0005	6	1	**0.035**
Closure	Upper Case	0.387	0.0005	6	1	**0.056**
Post-closure	Base Case	0.002	0.0005	6	1	0.001
Post-closure	Upper Case	0.003	0.0005	6	1	0.001
	Maintain SC0 under the FWAL guideline	0.130	0.0005	6	1	0.019

Notes: C_1 = source concentration at BJ 3.10 or BJ 2.62
C_2 = background concentration in upper Sulphurets Creek
C_f = final concentration at SC0
V_1 = flow at BJ 3.10 or BJ 2.62 (set to 1)
V_2 = flow at SC0 (set to 6).

Solving the mass balance equation for C_1 when the final concentration at SC0 is set to 0.019 mg-N/L (just below the BC FWAL guideline) shows that a discharge of up to 0.13 mg-N/L at BJ 3.10 will not cause the concentration at SC0 to increase above the BC FWAL guideline.

5.8.3 Magnitude

The PE-107835 discharge limit of 0.24 mg-N/L was developed to be protective aquatic life in Brucejack Creek from chronic toxicity. Modelled concentrations during operations are between 0.5 and 1 times the discharge limit (Table 5-9); therefore, the magnitude of potential effects to aquatic life during operations is **medium**. The maximum Base Case modelled concentrations during closure is equal to the discharge limit, and the maximum Upper Case concentration is above the discharge limit (Table 5-9); therefore, the magnitude of potential effects to aquatic life during closure is **high**. During post-closure, nitrite is modelled to decrease to baseline levels; therefore, the magnitude during post-closure is **low**.

Table 5-9:
Modelled nitrite concentrations compared to the PE-107835 discharge limit.

Mine Phase	Model	Maximum Modelled (mg-N/L)	Discharge Limit (mg-N/L)	Exceedance Factor
Operations	Base Case	0.128	0.24	0.5 x
Operations	Upper Case	0.208	0.24	0.9 x
Closure	Base Case	0.244	0.24	1.0 x
Closure	Upper Case	0.387	0.24	1.6 x
Post-closure	Base Case	0.002	0.24	0.01 x
Post-closure	Upper Case	0.003	0.24	0.01 x

5.8.4 Duration, Frequency, and Reversibility

Only the Upper Case model results exceed the nitrite discharge limit, and only seasonally during closure (Figure 5-11). The duration of these exceedances of discharge limits is categorized as **medium-term** and the frequency is **regular**. Base Case model results are categorized as **none** for both duration and frequency because they do not exceed the discharge limit during any mine phase.

The Base Case and Upper Case nitrite results return to concentrations near baseline levels during post-closure; therefore, the effects of mining on nitrite levels are **reversible**, for both the Base Case and Upper Case.

5.8.5 Consequence

Adverse effects to aquatic life from modelled nitrite concentrations during operations are not expected, since concentrations do not exceed a discharge limit, for both Base Case and Upper Case; therefore, the consequence of modelled nitrite concentrations during operations is categorized as **Level 1**.

The maximum Base Case modelled concentrations during closure peak at a concentration equal to the discharge limit. Since Base Case modelled concentrations do not go above the level that was developed to be protective of aquatic life in Brucejack Creek no toxicity is expected from the modelled concentration. The closure peak has a regional geographic extent, but the species inhabiting upper Sulphurets Creek are similar to those in Brucejack Creek and modelled nitrite levels are not expected to cause toxicity. Therefore, the consequence for Base Case during closure is categorized as **Level 1.**

The Upper Case peaks at 1.6 times the discharge limit during closure. The closure peaks have a regional geographic extent and a high magnitude. The duration of Upper Case exceedance of discharge limits is medium-term and the frequency is regular. Increases to nitrite concentrations in Brucejack Creek are reversible. The ecological context of the receiving environment is low. Nitrite is a macronutrient for periphyton, and periphyton grow well in nitrite concentrations well above the modelled concentrations. There is no potential for adverse effects to fish, fish habitat, or threatened species. There is potential for the Upper Case peaks during closure to cause chronic toxicity to invertebrates in Brucejack Creek. The resiliency of aquatic life in the receiving environment is high. Considering these factors, the potential consequence of Upper Case modelled concentrations during closure are minor effects, such as reduced growth rate or reduced fecundity, to a portion of the ecosystem (**Level 2**).

Post-closure nitrite concentrations are below the discharge limit for both Base Case and Upper Case models, and no adverse effects to aquatic life in Brucejack Creek are expected (**Level 1**).

5.8.6 Likelihood

Modelled concentrations during operations are likely an overestimate, for both the Base Case and Upper Case models, as seen from the comparison of measured and modelled nitrite from 2017 through 2021 (Figure 5-11). Modelled concentrations during closure may also be an overestimate, although there is higher uncertainty if nitrification processes that occur in the WRTSF will also occur at the same rate in the flooded underground mine. Pretium has developed a Closure Underground Water Quality Management Plan (Pretium, 2018b) to ensure that the underground mine pool water quality is suitable for discharge before reaching its spilling elevation (~1355 masl). The plan also identifies monitoring programs required to manage the potential risk to water quality in Brucejack Creek

associated with flooding at closure. The opportunity to improve mitigation of nitrite in flooded underground mine water makes it unlikely that closure peaks will be as high as currently modelled.

Given that Base Case and Upper Case modelled concentrations during operations are less than the discharge limit, adverse effects to aquatic life during operations are **very unlikely**. During closure, Base Case nitrite concentrations peak at a concentration equal to the discharge limit, and adverse effects from Base Case closure concentrations are **very unlikely.** Upper Case nitrite during closure is up to 1.6 times higher than the discharge limit. It is likely that toxicity to sensitive species would occur at the modelled Upper Case peak concentrations during closure, but it is expected that mitigation measures implemented at closure will result in nitrite levels in Brucejack Creek that are below the discharge limit, for both the Base Case and Upper Case; therefore, adverse effects to aquatic life during closure are **unlikely** for the Upper Case.

Modelled nitrite during post-closure decrease to levels below the discharge limit, and adverse effects from nitrite are **very unlikely** during post-closure, for both the Base Case and Upper Case.

5.8.7 Risk

During operations and post-closure both Base Case and Upper Case model results have a Level 1 consequence and are very unlikely to cause toxicity; therefore, the risk of adverse effects from modelled nitrate levels is **low** (Figure 5-2). During closure, the Base Case consequence is Level 1 and adverse effects are very unlikely; therefore, the risk of adverse effects is **low**. Upper Case during closure has a Level 2 consequence and is unlikely to cause adverse effects; therefore, the risk rating is **low** (Figure 5-2).

5.8.8 Confidence

The comparison of modelled concentrations to five years of monitoring data illustrate that the Base Case typically overestimates nitrite levels at BJ 3.10 and BJ 2.62, and that measured concentrations are consistently well below the Upper Case results. This lengthy monitoring dataset provides high confidence that the Base Case modelled nitrite concentrations represent the expected concentrations in Brucejack Creek, and that the Upper Case model overestimates nitrite levels during operation.

The low ecological context of the receiving environment, and the site-specific discharge limit developed for protection of aquatic life in Brucejack Creek used as a benchmark for potential adverse effects to aquatic life from modelled nitrite levels, provide **high** confidence that the risk ratings for nitrite are accurate.

5.8.9 Summary

The risk of toxicity from Base Case and Upper Case modelled nitrite concentrations is categorized as low for all mine phases (Table 5-10).

Table 5-10:
Summary of effects assessment ratings for toxicity potential from modelled nitrite concentrations.

	Base Case			Upper Case		
	Operations	**Closure**	**Post-closure**	**Operations**	**Closure**	**Post-closure**

Risk	low	low	low	low	low	low
Confidence	high	high	high	high	high	high

5.9 Sulfate

Sulfate was identified as POPC based on its modelled concentration being greater than 80% of the BC FWAL guideline (Section 4.2). The identification of POPCs conservatively used baseline hardness for calculating guidelines that are hardness dependent, which includes the sulfate guideline. The release of the SO_4^{2-} anion from mined material is accompanied by release of Ca^{2+} and Mg^{2+} cations. This means that hardness will increase as sulfate concentration increases, as has been observed in water quality monitoring at BJ 3.10.

Comparison of Base Case modelled sulfate concentrations to the long-term FWAL guideline calculated using the Base Case modelled hardness indicates that sulfate levels will remain below the guideline throughout the life of mine (Figure 5-13). Monitoring of sulfate in Brucejack Creek indicates that concentrations have been slightly greater than the Base Case model, but well below the Upper Case model, and that the Base Case model is representative of expected sulfate concentrations in Brucejack Creek. Since sulfate is expected to remain below its FWAL guideline, sulfate is not a POC and no further assessment related to effects on aquatic life in Brucejack Creek has been carried out for sulfate.

Figure 5-13: Modelled sulfate concentrations at BJ 3.10 (top) and BJ 2.62 (bottom) compared to the hardness dependent BC FWAL guideline and to measured concentrations.

5.10 Dissolved Aluminum

Dissolved aluminum was identified as a POPC because the maximum Base Case model predictions at BJ 3.10 (0.062 mg/L) and BJ 2.62 (0.057 mg/L) are above the long-term FWAL guideline of 0.05 mg/L (Figure 5-14). Base Case modelled D-Al concentrations are highest early in operations and decrease below FWAL guidelines later in operations as the amount of waste rock (the dominant source of loadings) placed in the WRTSF decreases.

Although there have been sporadic water quality samples from BJ 3.10 that had D-Al concentrations above the long-term FWAL guideline, most measurements have been below the guideline and below Base Case model predictions. The increase in D-Al concentrations at BJ 3.10 that is seen in the Base Case model during operations has not been observed from the weekly measurements made at BJ. 3.10. The observation of sporadic elevated D-Al concentrations at BJ 3.10 is attributed to relatively high TSS episodes and the associated presence of colloidal Al particles which may pass through the 0.45 µm filter that is operationally used to define the dissolved fraction.

The Base Case and Upper Case models are considered to overpredict D-Al concentrations since the model employs a mass balance approach and does not account for solubility-controlled precipitation reactions which are expected to occur in the WRTSF. For this reason, concentrations above the long-term guideline are not anticipated over life of mine.

D-Al is therefore not considered a POC and no further assessment related to effects to aquatic life in Brucejack Creek has been carried out for D-Al.

Figure 5-14: Modelled dissolved aluminum concentrations at BJ 3.10 (top) and BJ 2.62 (bottom) compared to the BC FWAL guidelines and to measured concentrations.

5.11 Total Arsenic

5.11.1 Introduction

Arsenic levels in Brucejack Creek have increased since mine operations began in 2017, in agreement with the Base Case model (Figure 5-15). The maximum modelled T-As concentration during operations is 0.0137 mg/L (13.7 µg/L) for the Base Case model and 0.0259 mg/L (25.9 µg/L) for the Upper Case model. T-As levels in Brucejack Creek are expected to increase during the first year of closure when water from the flooded underground mine first reports to Brucejack Creek, then decline. The peak concentrations during closure are 0.0111 mg/L for the Base Case and 0.0268 mg/L for the Upper Case. Post-closure T-As is expected to stabilize with annual maxima of 0.0032 mg/L for the Base Case. Post-closure Upper Case T-As levels are higher than the current discharge limit, with annual maxima of 0.0145 mg/L.

The current discharge limit in in PE-107835 is 0.010 mg/L. The discharge limit was established as part of the permit amendment for the 3800 tpd production rate (Pretium, 2018b). It was set at the maximum Upper Case model result during operations, and site-

specific toxicity test results that indicated 0.010 mg/L is unlikely to cause toxicity to aquatic life in Brucejack Creek. Arsenic concentrations in the WRTSF are higher for the 4950 tpd models than they were for the 3800 tpd models, largely due to the higher rates of waste rock and tailings deposition to the WRTSF, as well as to the change in modelled lake turnover from twice a year for the 3800 tpd model to once a year in the 4950 tpd model.

Figure 5-15: Modelled total arsenic concentrations at BJ 3.10 (top) and BJ 2.62 (bottom) compared to the PE-107835 discharge limit and to measured concentrations.

5.11.2 Geographic Extent

The geographic extent of effects to T-As concentrations is assessed by estimating if concentrations in upper Sulphurets Creek, at SC0, have the potential to become elevated above the long-term WQG (0.005 mg/L). This is done using a mass balance equation and a minimum mixing ratio of 6:1 (parts SC0 to parts Brucejack Creek water) (see section 5.5).

Total arsenic concentrations measured at SC0, in upper Sulphurets Creek, are strongly affected by seasonality (Figure 5-16). During open water months, glacial melt contributes high levels of TSS to Sulphurets Creek which results in T-As concentrations that are greater than the BC FWAL guideline of 0.005 mg/L. During winter months, T-As at SC0 is markedly lower, ranging from 0.0003-0.0032 mg/L. Although T-As concentrations in Brucejack Creek have increased since mine operations began, a noticeable change to T-As

at SC0 has not been observed. The median baseline concentration during sQ4 was 0.0013 mg/L. The median T-As concentration from the seven samples collected in December from 2013 through 2021 is 0.0005 mg/L. This latter concentration is used in the mass balance equation for determining geographic extent as it better represents background levels than the higher baseline concentration.

Figure 5-16: Total arsenic concentrations in upper Sulphurets Creek measured quarterly since baseline.

Total arsenic concentrations of ≤0.0313 mg/L in Brucejack Creek will ensure that concentrations at SC0 are less than the BC FWAL guideline when there is minimal dilution available (Table 5-11). The maximum modelled T-As concentration during all mine phases is 0.0268 mg/L (Upper Case model during closure). Since all modelled concentrations are less than 0.0313 mg/L, all model scenarios do not have the potential to elevate T-As at SC0 to concentrations above the FWAL guideline; therefore, the geographic extent of changes to water quality is **local** for both the Base Case and Upper Case.

Table 5-11:
Final total arsenic conentration in upper Sulphurets Creek for maximum modelled concentrations in Brucejack Creek during different mine phases.

Mine Phase	Model	C_1 (mg-N/L)	C_2 (mg-N/L)	V_2	V_1	C_f (mg-N/L)
Operations	Base Case	0.0137	0.0005	6	1	0.0024
Operations	Upper Case	0.0259	0.0005	6	1	0.0041
Closure	Base Case	0.0111	0.0005	6	1	0.0020
Closure	Upper Case	0.0268	0.0005	6	1	0.0043
Post-closure	Base Case	0.0032	0.0005	6	1	0.0009
Post-closure	Upper Case	0.0145	0.0005	6	1	0.0025
	Maintain SC0 under the FWAL guideline	0.0313	0.0005	6	1	0.0049

Notes: C_1 = source concentration at BJ 3.10 or BJ 2.62
C_2 = background concentration in upper Sulphurets Creek
C_f = final concentration at SC0
V_1 = flow at BJ 3.10 or BJ 2.62 (set to 1)
V_2 = flow at SC0 (set to 6).

5.11.3 Magnitude

The PE-107835 discharge limit of 0.01 mg/L was developed based on the Upper Case modelled concentration during operations for the 3800 tpd production rate, and a site-specific toxicity test that demonstrated that 0.01 mg/L T-As is unlikely to cause to toxicity to aquatic life in Brucejack Creek. The bioassay was done using a species of algae (*Pseudokirchneriella subcapitata*), since algae are known to be more sensitive to chronic toxicity from arsenic than are invertebrates, and algal toxicity tests are the basis for the BC FWAL guideline. This test was done in 2017 using water collected from BJ 3.10 and spiked with arsenic. The test produced a low effect chronic toxicity endpoint (IC20 for growth) of 0.0376 mg/L (Table 5-12). The *P. subcapitata* bioassay of arsenic in Brucejack Creek water was repeated in 2018 (IC20 = 0.0931 mg/L) and again in 2021 (IC20 = 0.0980 mg/L) (Table 5-12). All three toxicity tests were conducted by Nautilus Environmental. Test reports are presented in Appendix D.

Table 5-12:
Chronic toxicity endpoints from Pseudokirchneriella subcapitata bioassays of BJ 3.10 water spiked with arsenic.

Collection date	IC20 for growth
October 30, 2017	0.0376 mg/L
June 25, 2018	0.0931 mg/L
June 14, 2021	0.0980 mg/L
Geometric mean	0.0700 mg/L

The BC protocol for the derivation of FWAL guidelines says "If there is more than one comparable record (i.e. same species, same life stage, same endpoint, same exposure duration), then the species effects endpoint is to be represented by the geometric mean of these records." (MECCS, 2019). The three toxicity tests of BJ 3.10 water with added arsenic meet these criteria for being comparable records. The geometric mean of the three tests, 0.070 mg/L, will be used as the environmental benchmark for assessing the magnitude of potential toxicity from modelled T-As concentrations for the 4950 tpd production rate.

The 4950 tpd model results are less than half the chronic toxicity threshold of 0.070 mg/L, for Base Case and Upper Case model results, during all mine phases (Table 5-13). This comparison to the toxicity threshold indicates that the potential for modelled T-As concentrations to cause toxicity to aquatic life in Brucejack Creek has a **low** magnitude.

Table 5-13:
Modelled arsenic concentrations compared to the low-effect chronic toxicity endpoint from site-specific bioassays.

Mine Phase	Model	Maximum Modelled (mg/L)	Toxicity Benchmark (mg/L)	Exceedance Factor
Operations	Base Case	0.0137	0.070	0.20 ×
Operations	Upper Case	0.0259	0.070	0.37 ×
Closure	Base Case	0.0111	0.070	0.16 ×
Closure	Upper Case	0.0268	0.070	0.38 ×
Post-closure	Base Case	0.0032	0.070	0.05 ×
Post-closure	Upper Case	0.0145	0.070	0.21 ×

5.11.4 Duration, Frequency, and Reversibility

Base Case and Upper Case modelled concentrations of T-As are less than half of the environmental benchmark of 0.070 mg/L throughout the life of mine. Thus, the modelled concentrations of T-As in Brucejack Creek for both model cases are categorized as **none** for duration and frequency. Base Case T-As levels decrease to near baseline levels during post-closure; therefore, the Base Case modelled changes to T-As concentrations are **reversible**. Upper Case is modelled to stabilize with annual maxima of 0.0145 mg/L during post-closure. Since this concentration is well above the baseline levels, the Upper Case model results are considered **irreversible**.

5.11.5 Consequence

Toxicity to aquatic life in Brucejack Creek from Base Case modelled T-As levels is not expected, since the maximum modelled concentration is 5 times lower than the chronic

toxicity threshold of 0.070 mg/L developed from bioassays that tested the toxicity of arsenic in Brucejack Creek water (Table 5-13). Since the ecological context of Brucejack Creek is low, and no toxicity to aquatic life in Brucejack Creek is expected, the potential consequence of the Base Case modelled T-As concentrations is low (**Level 1**).

Toxicity to aquatic life in Brucejack Creek from Upper Case modelled T-As levels is not expected, since the maximum modelled concentration is 2.6 times lower than the site-specific toxicity threshold (Table 5-13). Since the ecological context of Brucejack Creek is low, and no toxicity to aquatic life in Brucejack Creek is expected, the potential consequence of the Upper Case modelled T-As concentrations is low (**Level 1**).

5.11.6 Likelihood

To date, T-As concentrations at BJ 3.10 have been well represented by the Base Case model and overestimated by the Upper Case model (Figure 5-15). Base Case modelled T-As concentrations are likely to occur, but toxicity to aquatic life in Brucejack Creek from Base Case concentrations is **very unlikely**.

Monitoring of T-As concentrations at BJ 3.10 and BJ 2.62 indicate that the Upper Case model produces an overestimate of potential T-As levels in Brucejack Creek, which are very unlikely to occur. If Upper Case T-As levels do occur, it is unlikely that toxicity will occur to aquatic life in Brucejack Creek. Considering the likelihood of Upper Case occurring and the likelihood of toxicity, adverse effects to aquatic life from Upper Case modelled concentrations is categorized as **very unlikely**.

5.11.7 Risk

Both Base Case and Upper Case model results have a Level 1 consequence and are very unlikely to cause toxicity; therefore, the risk of adverse effects from modelled T-As levels is **low**, for both the Base Case and Upper Case (Figure 5-2).

5.11.8 Confidence

The comparison of modelled T-As concentrations to five years of monitoring data provides high confidence that the Base Case model well represents expected T-As concentrations for the 4950 tpd production rate, and that the Upper Case model overestimates T-As levels in Brucejack Creek. The site-specific toxicity testing that was done provides a direct measure of toxicity to species that are representative of aquatic life in Brucejack Creek, which provides a high level of confidence in the assessment of potential toxicity from modelled T-As levels. Overall, there is **high** confidence in the assessment of potential risk to aquatic life from the modelled T-As concentrations.

5.11.9 Summary

The risk of toxicity from Base Case and Upper Case modelled arsenic concentrations is categorized as low for all mine phases (Table 5-14).

Table 5-14:
Summary of effects assessment ratings for toxicity potential from modelled total arsenic concentrations.

5.12 Dissolved Copper

5.12.1 Introduction

Modelled D-Cu concentrations at BJ 3.10 increase throughout operations (Figure 5-17). The Base Case model shows that D-Cu is expected to increase to greater than the BC FWAL guideline during operations. The BC FWAL guideline is calculated using a biotic ligand model (BLM) that uses site water quality as inputs. BJ 3.10 water is moderately soft and has dissolved organic carbon levels that are typically below detection limit. Based on these inputs, the BLM calculates a long-term WQG of 0.0003 mg/L (0.3 µg/L) that is slightly greater than the routine analytical detection limit of 0.0002 mg/L (0.2 µg/L) that is provided by ALS Environmental laboratory. The maximum Base Case result during operations is 0.00042 mg/L (0.42 µg/L) and the maximum Upper Case during operations is 0.00087 mg/L (0.87 µg/L).

The D-Cu concentrations modelled at BJ 2.62 during closure are much higher than during operations, due to loadings from the flooded underground mine that report to Brucejack Creek through groundwater pathways. The maximum BJ 2.62 concentration during closure

is 0.00171 mg/L (1.71 µg/L) for the Base Case and 0.01052 (10.52 µg/L) for the Upper Case.

PE-107835 does not set a discharge limit at BJ 3.10 for D-Cu. D-Cu was not identified as a POPC in the application to increase the production rate to 3800 tpd (Pretium, 2018b) because the BC FWAL guideline was much higher at the time the application was submitted. The BLM-derived guidelines went into effect in 2019.

Figure 5-17: Modelled dissolved copper concentrations at BJ 3.10 (top) and BJ 2.62 (bottom) compared to the BC FWAL guidelines and to measured concentrations.

5.12.2 Geographic Extent

The geographic extent of changes to water quality is defined as local if the modelled concentrations do not elevate concentrations at SC0 in upper Sulphurets Creek above the FWAL guideline, and regional if the modelled concentrations have the potential to cause SC0 concentrations to increase to greater than the FWAL guideline. Dissolved copper levels measured at SC0 from 2015 through 2021 are typically above the long-term FWAL guideline of 0.0003 mg/L (Table 5-15 and Figure 5-18). The high D-Cu levels that have been measured at SC0 are considered to be naturally occurring, and not induced by loadings from Brucejack Creek, because most BJ 3.10 and BJ 2.62 samples have had D-Cu concentrations below the detection limit of 0.0002 mg/L. Five of the 31 samples from SC0 had D-Cu levels greater than the peak Upper Case modelled concentration at BJ 2.62 (0.011 mg/L). During operations, the maximum Base Case concentration (0.00042 mg/L)

is less than the median D-Cu concentration at SC0, and the maximum Upper Case modelled concentration (0.00087 mg/L) is less than the average concentration at SC0. Because the typical D-Cu concentrations at SC0 are higher than Base Case and Upper Case modelled concentrations of D-Cu in Brucejack Creek, during all mine phases, the geographic extent of the modelled concentrations is categorized as **local**.

Table 5-15:
Summary statistics of dissolved copper concentrations in water quality samples collected at SC0 from 2015 through 2021.

Statistic	Concentration	Units
# samples	31	mg/L
Maximum	0.02150	mg/L
75th percentile	0.00578	mg/L
Median	0.00059	mg/L
Average	0.00417	mg/L
25th percentile	0.00033	mg/L
Minimum	0.00020	mg/L

Figure 5-18: Dissolved copper concentrations in upper Sulphurets Creek measured quarterly since baseline.

5.12.3 Magnitude

The potential for D-Cu to cause toxicity to aquatic life in Brucejack Creek was assessed by conducting toxicity tests using water collected from BJ 3.10 and spiked with copper. The BJ 3.10 sample was collected on January 10, 2022 and shipped to Nautilus Environmental for testing. Species tested were the algae *Pseudokirchneriella subcapitata*, the duckweed *Lemna minor*, and the invertebrates *Ceriodaphnia dubia* and *Chironomus dilutus*. *P. subcapitata* and *C. dilutus* represent taxa commonly occurring in Brucejack Creek, and *C.*

dubia and *L. minor* are species of aquatic invertebrate and aquatic plant that the BLM model indicates are sensitive to chronic toxicity from D-Cu.

The Nautilus lab report from the site-specific D-Cu bioassays is provided as Appendix E. Acute toxicity to *C. dubia* occurred at 0.0122 mg/L (LC50 or median lethal endpoint) (Table 5-16). The acute toxicity endpoint for the chironomid *C. dilutus* was higher than any of the concentrations tested, up to 0.0310 mg/L. The plant and algae bioassays only tested growth, so did not have acute toxicity endpoints.

Table 5-16:
Results of toxicity testing of dissolved copper in BJ 3.10 water.

Endpoint	Units	*P. subcaptitata*	*L. minor* (frond count)	*L. minor* (dry wt.)	*C. dubia*	*C. dilutus*
Survival LC50	mg/L				0.0122	>0.0310
Growth or Reproduction IC20	mg/L	0.0023	0.0029	0.0034	0.0052	>0.0310
Growth or Reproduction IC50	mg/L	0.0166	>0.0103	>0.0103	0.0109	>0.0310

The aquatic plants and algae were more sensitive to chronic toxicity from D-Cu than the invertebrates species (Table 5-16). The lowest chronic endpoint was an IC20 of 0.0023 mg/L for the algae *P. subcapitata*. This is the concentration that caused a 20% reduction in growth rate of this algae. Note that the duckweed test measures growth in two ways: as the number of fronds that grow over the 7 day test and as the increase in dry weight over the 7 day test. The IC20 for frond count was slightly higher that the IC20 for growth of *P. subcapitata*. The lowest chronic endpoint from these bioassays (0.0023 mg/L) will be used as the toxicity benchmark for assessing the magnitude of potential toxicity from modelled concentrations of D-Cu in Brucejack Creek.

During operations both the Base Case and Upper Case model results are below the toxicity benchmark (Table 5-17). The peak concentrations that are modelled to occur during closure have the potential to cause chronic toxicity to sensitive species for the Base Case. The Upper Case peak is greater than the LC50 for *C. dubia* (Table 5-17); therefore, has the potential to cause acute toxicity to sensitive species. During post-closure, D-Cu concentrations decrease and stabilize at concentrations similar to operations.

Table 5-17:
Modelled dissolved copper concentrations compared to the low-effect chronic toxicity benchmark from site-specific bioassays.

Mine Phase	Model	Maximum Modelled (mg/L)	Toxicity Benchmark (mg/L)	Exceedance Factor
Operations	Base Case	0.00042	0.0023	0.18 ×
Operations	Upper Case	0.00087	0.0023	0.38 ×
Closure	Base Case	0.00171	0.0023	0.74 ×
Closure	Upper Case	0.01052	0.0023	4.57 ×
Post-closure	Base Case	0.00046	0.0023	0.20 ×
Post-closure	Upper Case	0.00109	0.0023	0.47 ×

The 4950 tpd model results during operations and post-closure are less than half the chronic toxicity threshold for both the Base Case and Upper Case; therefore, the magnitude of potential effects during operations and post-closure is categorized as **low**. During closure, the maximum Base Case model concentration is slightly less than the chronic toxicity benchmark; therefore, the magnitude of potential effect is categorized as **medium**. The maximum Upper Case concentration during closure has the potential to cause acute toxicity; therefore, the magnitude of potential effects is **high**.

5.12.4 Duration, Frequency, and Reversibility

Base Case and Upper Case modelled concentrations of D-Cu are less than half of the environmental benchmark of 0.0023 mg/L during operations and during post-closure. Thus, the modelled concentrations of D-Cu in Brucejack Creek during operations and during post-closure, for both model cases, are categorized as **none** for duration and frequency.

During closure, the Base Case D-Cu concentration is less than half of the environmental benchmark except for 3 months during the first year of closure; therefore, the duration is classified as **medium-term** and the frequency is classified as **regular**. During closure, the Upper Case D-Cu concentrations are seasonally greater than the environmental benchmark for each of the closure years; therefore, the duration is classified as **long-term**, the frequency is classified as **regular**.

Base Case D-Cu levels decrease to near baseline levels during post-closure; therefore, the Base Case modelled changes to D-Cu concentrations are **reversible**. Upper Case is modelled to stabilize with annual maxima of 0.00111 mg/L during post-closure. Since this concentration is well above the baseline levels, the Upper Case model results are considered **irreversible**.

5.12.5 Consequence

During operations and post-closure, toxicity to aquatic life in Brucejack Creek is not expected, for both the Base Case and Upper Case models, since maximum modelled concentrations are less than half the site-specific chronic toxicity benchmark (Table 5-17). Since the ecological context of Brucejack Creek is low, and no toxicity to aquatic life in Brucejack Creek is expected, the potential consequence of the Base Case and Upper Case modelled D-Cu concentrations is low (**Level 1**) during operations and post-closure.

During closure, there is potential for chronic toxicity to sensitive species from the maximum Base Case modelled concentration. This potential for minor effects on the biological ecosystem during closure makes the consequence **Level 2**. The Upper Case during closure has higher potential to cause chronic toxicity, and has the potential to cause acute toxicity to sensitive species. Given the low ecological context, the Upper Case during closure has the potential to cause moderate, short-term effects to the ecosystem which is categorized as **Level 3**.

5.12.6 Likelihood

To date, D-Cu concentrations at BJ 3.10 have typically been less that the Base Case model. The Upper Case model has overestimated D-Cu concentrations at BJ 3.10 and BJ 2.62. Episodes of D-Cu concentrations at BJ 3.10 that are greater than the Base Case and Upper Case model have occurred in association with elevated TSS. These monitoring results indicate that the Base Case model better represents D-Cu concentrations during operations. Toxicity to aquatic life in Brucejack Creek from Base Case concentrations during operations and post-closure is **very unlikely**.

There is uncertainty if Base Case modelled concentrations during closure will continue to be an overestimate of actual concentrations, since the sources of D-Cu change, as does the use of the water treatment plant and the pathway of loadings to Brucejack Creek. The Upper Case concentrations during closure are much higher than Base Case, and are less likely to occur than Base Case. The modelled closure scenario has accelerated flooding of the underground mine and recirculation of water through the water treatment plant for 15 months post-operations. Other mitigation scenarios have not yet been modelled, but will be modelled as part of closure planning for the underground mine. A Closure Underground Water Quality Adaptive Management Plan (Pretium, 2020e) was developed to describe potential mitigation options available to manage the flushing concentration peaks and ensure that underground mine pool water quality is suitable for discharge before reaching its spilling elevation (~1355 masl). The plan also identifies monitoring programs required to manage the potential risk associated with flooding at closure.

The opportunity to improve mitigation of D-Cu in flooded underground mine water makes it unlikely that closure peaks will be as high as currently modelled. Given that there is

potential for chronic toxicity to occur during closure to species that are sensitive to copper toxicity from the Base Case modelled D-Cu levels, but the modelled peaks during closure are unlikely to occur, the likelihood of toxicity to aquatic life in Brucejack Creek during closure is categorized as **unlikely** for the Base Case. Given that it is highly unlikely that Upper Case peaks during closure will occur, the likelihood of toxicity to aquatic life in Brucejack Creek during closure is also categorized as **unlikely** for the Upper Case.

5.12.7 Risk

During operations and post-closure, both Base Case and Upper Case model results have a Level 1 consequence and are very unlikely to cause toxicity; therefore, the risk of adverse effects from modelled D-Cu levels is **low** (Figure 5-2).

During closure, the Base Case has Level 2 consequence and is unlikely to cause toxicity; therefore, the risk of the Base Case causing adverse effects during closure is **low**.

During closure, the Upper Case has Level 3 consequence and is unlikely to cause toxicity; therefore, the risk of the Upper Case causing adverse effects during closure is **moderate**.

5.12.8 Confidence

The comparison of modelled D-Cu concentrations to five years of monitoring data provides high confidence that the Base Case model well represents expected D-Cu concentrations during operations, and that the Upper Case is an overestimate of D-Cu during operations. The site-specific toxicity testing that was done provides a direct measure of toxicity to species that are representative of aquatic life in Brucejack Creek, which provides a high level of confidence in the assessment of potential toxicity from modelled D-Cu levels to aquatic life in the receiving environment. Thus, there is **high** confidence in the assessment of potential risk to aquatic life from the modelled D-Cu concentrations during operations.

There is moderate confidence that observed D-Cu concentrations in Brucejack Creek will continue to be lower than the Base Case model during closure and post-closure. It is likely that closure planning will be able to mitigate the peak D-Cu concentrations that are modelled to occur during closure. The moderate uncertainty in how well the models represent D-Cu during closure provides **moderate** confidence in the assessment of risk to aquatic life in Brucejack Creek during closure.

The site-specific toxicity testing that indicates post-closure modelled concentrations of D-Cu have a low risk to aquatic life and provides **high** confidence in the assessment of risk during post-closure.

5.12.9 Summary

The risk of toxicity from Base Case and Upper Case modelled copper concentrations is categorized as low for all mine phases, except for the Upper Case during closure which has a moderate risk rating (Table 5-18).

Table 5-18:
Summary of effects assessment ratings for toxicity potential from modelled dissolved copper concentrations.

5.13 Total Selenium

5.13.1 Introduction

Measured concentrations of T-Se at BJ 3.10 and BJ 2.62 have been well represented by the Base Case model (Figure 5-19). Base Case modelled T-Se has a maximum concentration during operations of 0.0021 mg/L, which is slightly greater than the BC FWAL guideline of 0.0020 mg/L. The peak concentration during closure is 0.0037 mg/L. T-Se is modelled to decrease during closure and post-closure to steady state concentrations with an annual range of 0.0002-0.0005 mg/L.

Measured concentrations of T-Se have been below the Upper Case modelled concentrations. The Upper Case has a maximum concentration during operations of 0.0062 mg/L and a peak during closure of 0.0150 mg/L. Upper Case T-Se concentrations decrease during closure and post-closure to steady state concentrations with an annual range of 0.0003-0.0011 mg/L.

Figure 5-19: Modelled total selenium concentrations at BJ 3.10 (top) and BJ 2.62 (bottom) compared to the BC FWAL guideline and to measured concentrations.

The BC FWAL guidelines for Se were developed based on the taxa shown to be most sensitive to Se exposure, namely fish and aquatic birds (BCMOE 2014). It is generally thought that algae and invertebrates are fairly tolerant to elevated Se concentrations, and the more important role these organisms play is in the transfer of Se into the aquatic food web (Janz *et al.*, 2010). Inorganic Se in water can be taken up by primary producers, such as periphyton, and incorporated into tissues as organic forms of Se. These organic Se forms have the potential to bioaccumulate in higher trophic levels to tissue concentrations that can cause reproductive impairments, such as decreased fertility, reduced egg hatchability, and increased frequency of deformity in embryos.

5.13.2 Ecological Context

Egg laying vertebrates (fish, aquatic birds, and amphibians) are potential receptors for adverse effects from Se in water. Fish are not present in Brucejack Creek or upper Sulphurets Creek (Rescan, 2013a). A fish barrier is present near the mouth of Sulphurets Creek, approximately 1.3 km upstream from the Unuk River. No fish occur upstream of this barrier, meaning the nearest fish-bearing water to the WRTSF is approximately 23 km downstream.

Baseline monitoring of waterbirds found that riverine birds, such as American dippers, were present outside of the local study area but were not observed in the Brucejack Creek area (Rescan 2013b). The baseline survey results indicate the birds that feed primarily on

benthic invertebrates in Brucejack Creek are uncommon or not present. An aquatic bird survey of the Brucejack Creek area was conducted in July 2022 to supplement the baseline survey results (ERM, 2022a; memo included as Appendix F). An aerial survey spotted seven shorebirds in the vicinity of Brucejack Creek, none of which could be identified. A ground survey found one sandpiper, one semipalmated plover, and feathers and scat of Canada goose in the vicinity of Brucejack Creek. None of the identified species are listed by the Committee on the Status of Endangered Wildlife in Canada (COSEWIC) or the British Columbia Conservation Data Centre. The memo notes that the sandpiper and plover observed in July could either be breeding residents or fall transients. Residents typically spend roughly three months in the area and rear young, meanwhile transients average closer to a four-day stay (Farmer and Durbian, 2006). While these species are present in the area, they have the potential to feed on aquatic insects in Brucejack Creek. Canada goose have the potential to consume food beside the creek but are not expected to feed on aquatic invertebrates in the creek.

A survey for amphibians along Brucejack Creek was also conducted in July 2022 (ERM, 2022a; Appendix F). No amphibians were observed. The memo concludes that Brucejack Creek is poor habitat for western toad (a provincially blue-listed species), because the elevation of the creek is too high and ponds thaw after the toad breeding season. In addition, the creek does not provide the very low flow and warm water that toads prefer.

Considering that Brucejack Creek does not contain fish or amphibians, and has the potential for a small number of birds to feed on benthic invertebrates in the creek during the short open-water season, the ecological context of Brucejack Creek for aquatic life to potentially experience adverse effects from selenium is considered **low**.

5.13.3 Geographic Extent

The geographic extent of effects to T-Se concentrations is assessed by estimating if concentrations in upper Sulphurets Creek, at SC0, have the potential to become elevated above the long-term WQG (0.002 mg/L). This is done using a mass balance equation and a minimum mixing ratio of 6:1 (parts SC0 to parts Brucejack Creek water) (see section 5.5).

Baseline median T-Se concentration at SC0 during sQ4 is 0.00027 mg/L. The maximum modelled T-Se concentration during the operations phase is 0.0062 mg/L. With minimal mixing ratio of 6:1, the maximum final concentration at SC0 during operations is 0.0011 mg/L, which is less than the BC FWAL guideline of 0.002 mg/L (Table 5-19). Because modelled discharge from the WRTSF does not increase concentration at SC0 to above the FWAL guideline, the geographic extent of effects to water quality during operations is **local**.

During closure, the maximum Base Case model result has the potential to raise T-Se concentration at SC0 to 0.0008 mg/L (Table 5-19); therefore, the geographic extent for Base Case during closure is **local**. The maximum Upper Case model result during closure has the potential to raise T-Se concentration at SC0 to 0.0024 mg/L (Table 5-19), which is above the FWAL guideline of 0.0020 mg/L; therefore, the geographic extent for Upper Case during closure is **regional**. If concentrations in Brucejack Creek reached the Upper Case peak concentration during closure, a mixing ratio of 8:1 would be needed to dilute T-Se to below the guideline, which is expected occur at SC0 except in the low flow months of December and January (Table 5-3).

The geographic extent during post-closure is **local** for both the Base Case and Upper Case.

Solving the mass balance equation for C_1 when the final concentration at SC0 is set to 0.0019 mg/L (just below the BC FWAL guideline) shows that a discharge of up to 0.0117 mg/L at BJ 3.10 will not cause the concentration at SC0 to increase above the BC FWAL guideline.

Table 5-19:
Final total selenium conentration in upper Sulphurets Creek for maximum modelled concentrations in Brucejack Creek during different mine phases.

Mine Phase	Model	C_1 (mg-N/L)	C_2 (mg-N/L)	V_2	V_1	C_f (mg-N/L)
Operations	Base Case	0.0021	0.00027	6	1	0.0005
Operations	Upper Case	0.0062	0.00027	6	1	0.0011
Closure	Base Case	0.0037	0.00027	6	1	0.0008
Closure	Upper Case	0.0150	0.00027	6	1	**0.0024**
Post-closure	Base Case	0.0005	0.00027	6	1	0.0003
Post-closure	Upper Case	0.0011	0.00027	6	1	0.0004
	Maintain SC0 under the FWAL guideline	0.0117	0.00027	6	1	0.0019

5.13.1 Magnitude

Potential adverse effects from elevated selenium levels in Brucejack Creek are toxicity to aquatic birds. The most direct means of determining the potential for toxic effects of Se in birds is through measurement of Se concentrations in eggs (BCMOE, 2014). The BC FWAL guideline for bird eggs is 6 µg/g dry weight. BC also developed a water quality guideline (0.002 mg/L) as an indirect measure of potential risk of toxic effects to fish and aquatic birds, because sampling water is much more commonly done and does not require sacrificing a bird egg. The T-Se water quality guideline provides a benchmark for assessing water quality model results.

The Base Case model during operations has a maximum concentration approximately equal to the guideline for protection of aquatic life (Table 5-20). The Upper Case model during operations has a maximum concentration that is 3.1 times the FWAL guideline. The peak in T-Se that is modelled to occur early in closure results in concentrations that are up to twice the FWAL guideline for the Base Case and 7.5 times the FWAL guideline for the Upper Case.

Table 5-20:
Modelled selenium concentrations compared to the BC FWAL guideline.

Mine Phase	Model	Maximum Modelled (mg/L)	FWAL guideline (mg/L)	Exceedance Factor
Operations	Base Case	0.0021	0.002	1.1 ×
Operations	Upper Case	0.0062	0.002	3.1 ×
Closure	Base Case	0.0037	0.002	1.8 ×
Closure	Upper Case	0.0150	0.002	7.5 ×
Post-closure	Base Case	0.0005	0.002	0.2 ×
Post-closure	Upper Case	0.0011	0.002	0.5 ×

The BC FWAL long-term guidelines are intended to protect the most sensitive species and most sensitive life stage against sub-lethal and lethal effects for indefinite exposures. Thus, model results that are less than or equal to the guideline will have a low potential to cause toxicity. The magnitude of the potential to cause toxicity should increase with increasing concentration of T-Se in water, because higher T-Se levels in water should cause higher tissue Se concentrations in benthic invertebrates which may be a source of food to birds. The magnitude of the potential to cause toxicity will also depend on the proportion of a bird's diet that comes from benthic invertebrates in Brucejack Creek, and the timing of foraging in Brucejack Creek. If tissue selenium concentrations of invertebrates in Brucejack Creek become elevated, then resident birds have a greater chance of accumulating Se in their eggs than do migrant individuals. As well, birds that feed on a Se rich diet while eggs are developing have a greater potential for toxic effects than birds that feed on Se rich diet only after the breeding season.

The aquatic birds that were observed in the vicinity of Brucejack Creek in July 2022 have the potential to be resident during the open water season, and to feed in Brucejack Creek before the breeding season. Therefore, water quality model results that are between 1 and 2 times the BC FWAL guideline will be categorized as having moderate potential to cause toxic effects, and concentrations greater than twice the guideline will be categorized as having a high potential. Thus, Base Case is **low** magnitude during operations, a **medium**

magnitude during closure, and a **low** magnitude during post-closure. Upper Case has a **high** magnitude during operations and closure, and a **low** magnitude during post-closure.

5.13.2 Duration, Frequency, and Reversibility

Base Case modelled concentrations of T-Se are seasonally slightly above the FWAL guideline for the last few years of operations, increase during the first year of closure, then decrease to below the guideline during post-closure (Figure 5-19). Thus, T-Se levels in Brucejack Creek for the Base Case model are categorized as being elevated for a **long-term** duration, occur **regularly**, and are **reversible**.

Upper Case modelled concentrations of T-Se are above the FWAL guideline for most of operations and closure, then decrease to below the guideline during post-closure. Thus, T-Se levels in Brucejack Creek for the Upper Case model are categorized as being elevated for a **long-term** duration, occur **continuously**, and are **reversible**.

5.13.3 Consequence

Elevated levels of T-Se in Brucejack Creek have the potential to bioaccumulate in benthic invertebrates. Brucejack Creek invertebrates are not a source of food to fish but may be food for the small number of aquatic birds that occur in the vicinity of Brucejack Creek. Base Case modelled concentrations of T-Se are not expected to result in toxic effects during operations (**Level 1**). Base Case modelled concentrations have the potential to cause toxic effects for one breeding season during closure (**Level 2**). Base Case results during post-closure are below the BC FWAL guideline (**Level 1**).

The Upper Case T-Se levels during operations and closure have potential to cause toxicity to a small populations of birds, but not to other parts of the Brucejack Creek ecosystem (**Level 3**). Upper Case results during post-closure are below the BC FWAL guideline (**Level 1**).

5.13.4 Likelihood

To date, T-Se concentrations at BJ 3.10 have been well represented by the Base Case model and overestimated by the Upper Case model (Figure 5-19). Base Case modelled T-Se concentrations are likely to occur, but toxicity to aquatic life from Base Case concentrations during operations is **very unlikely**. The Upper Case model has overestimated T-Se concentrations during the last 5 years of monitoring, and it is **very unlikely** that Upper Case concentrations will be observed during operations and result in toxicity to aquatic life.

During closure, the Base Case model is still the expected case and Upper Case modelled T-Se concentrations represent the upper range of potential changes to T-Se levels in Brucejack Creek. The modelled closure scenario includes mitigation measures of

accelerated flooding of the underground mine and recirculation of water through the water treatment plant for 15 months post-operations. Other mitigation scenarios that could reduce the peak T-Se concentrations during closure have not yet been modelled, but will be as part of closure planning. A Closure Underground Water Quality Adaptive Management Plan (Pretium, 2020e) was developed to describe potential mitigation options available to manage the flushing concentration peaks and ensure that the underground mine pool water quality is suitable for discharge before reaching its spilling elevation (~1355 masl). The plan also identifies monitoring programs required to manage the potential risk to water quality in Brucejack Creek associated with flooding at closure.

The opportunity to improve mitigation of T-Se in flooded underground mine water makes it unlikely that closure peaks will be as high as currently modelled. Given that there is potential for toxicity to aquatic birds during closure from the Base Case modelled T-Se levels, but the modelled peaks during closure are unlikely to occur, the likelihood of toxicity to aquatic life in Brucejack Creek during closure is categorized as **unlikely** for the Base Case. Given that it is highly unlikely that Upper Case peaks during closure will occur, the likelihood of toxicity to aquatic birds in the Brucejack Creek vicinity during closure is also categorized as **unlikely** for the Upper Case.

During post-closure, the likelihood of toxicity to aquatic birds in the Brucejack Creek vicinity is categorized as **very unlikely**, for both the Base Case and Upper Case.

5.13.5 Risk

During operations and post-closure, the Base Case model has Level 1 consequence and is very unlikely to cause toxicity; therefore, the risk of adverse effects is **low**. During closure, the Base Case model has Level 2 consequence and is unlikely to cause toxicity; therefore, the risk of adverse effects is **low**.

The Upper Case model has Level 3 consequence during operations and closure. Toxic effects to aquatic birds from Upper Case concentrations occurring during operations is highly unlikely, and is categorized as unlikely during closure. Thus, the risk of adverse effects from Upper Case T-Se levels is **low** during operations and **moderate** during closure. The post-closure, Upper Case consequence is Level 1 and the likelihood is very unlikely; therefore, the risk of adverse effects is **low**.

5.13.6 Confidence

Confidence that T-Se concentrations during operations are represented by the Base Case model is high, and that Base Case modelled T-Se concentrations will not cause toxicity is also **high**, since maximum concentrations are equal to the BC FWAL guideline.

There is uncertainty how T-Se levels that are greater than the BC FWAL guideline will bioaccumulate in the Brucejack Creek aquatic ecosystem. Aquatic birds are the potential

receptor for toxic effects from T-Se in Brucejack Creek. Selenium could cause toxicity to aquatic birds if it accumulates in the tissues of benthic invertebrates, and if the benthic invertebrates are a primary source of food for the birds prior to the breeding season. The assessment assumes that the birds that are present in the Brucejack Creek vicinity receive a high proportion of their diet from benthic invertebrates in the creek, and that they are resident populations that feed in Brucejack Creek prior to breeding and can accumulate selenium in their eggs. Given that these conservative assumptions were made about the potential for toxic effects to aquatic birds, and the uncertainty in the applicability of the bioaccumulation model used to derive the BC FWAL guideline to the Brucejack Creek ecosystem, the confidence in risk assessment ratings for model results that are greater than the BC FWAL guideline (Upper Case model during operations and closure, and the Base Case model during closure) is **moderate**. The confidence in post-closure ratings is **high**.

5.13.7 Summary

The risk of toxicity from Base Case and Upper Case modelled selenium concentrations is categorized as low for all mine phases (Table 5-21).

Table 5-21:
Summary of effects assessment ratings for toxicity potential from modelled dissolved copper concentrations.

	Base Case			Upper Case		
	Operations	**Closure**	**Post-closure**	**Operations**	**Closure**	**Post-closure**
Ecological context	low	low	low	low	low	low
Resiliency	high	high	high	high	high	high

Confidence	high	moderate	high	moderate	moderate	high

5.14 Human Health

Health Canada drinking water guidelines are designed to protect the health of the most vulnerable members of society, such as children and the elderly, from long-term exposure. The Assessment of Potential Health Effects carried out for the Application/EIS (Chapter 21 of Rescan, 2013) concluded that it is unlikely that people drink water from the Brucejack watershed. This conclusion was based on the inaccessibility of the watershed, the cold

weather during winter, absence of country foods such as fish in the area, and general low use of the Brucejack watershed by individuals from First Nations groups or the general public (Appendix 21-A of Chapter 21 of the Application/EIS; Rescan, 2013). There was no indication of Skii km Lax Ha or other First Nations obtaining drinking water from the Mine Site Area.

Since modelled concentrations in Brucejack Creek are above drinking water guidelines for some parameters, untreated Brucejack Creek water should not be used as the drinking water source for the mine camp. Mine camp drinking water is currently taken from a potable water well.

5.15 Summary of Risk Assessment of POCs

Model results were screened using ecological benchmarks, either discharge limits or BC FWAL guidelines for parameters that don't have discharge limits. Eight parameters were identified as parameters of potential concern using this screening method. Ammonia, sulfate, and D-Al were further evaluated and determined to not be parameters of concern. The remaining five parameters (nitrate, nitrite, T-As, D-Cu and T-Se) were assessed for Base Case and Upper Case modelled concentrations to cause adverse effects to aquatic life in Brucejack Creek, during each phase of mine life. The potential for modeled concentrations of POCs to cause toxic effects to aquatic life in Brucejack Creek was assessed. The potential for modeled concentrations of nitrate to cause eutrophication was also assessed. The potential risk of adverse effects was rated as low, for all POCs, for both Base Case and Upper Case, for all mine phases, with the exception of the Upper Case model result for T-Se during closure (Table 5-22). If Upper Case T-Se concentrations during closure are not mitigated, there is moderate risk for toxic effects to aquatic birds breeding in the vicinity of Brucejack Creek.

Table 5-22:
Summary of risk ratings for Base Case and Upper Case modelled concentrations of parameters of concern.

	Base Case			Upper Case		
	Operations	Closure	Post-closure	Operations	Closure	Post-closure
Nitrate (eutrophication)	low	low	low	low	low	low
Nitrate (toxicity)	low	low	low	low	low	low
Nitrite	low	low	low	low	low	low
Total arsenic	low	low	low	low	low	low
Dissolved copper	low	low	low	low	low	low
Total selenium	low	low	low	low	moderate	low

6 Summary

The Brucejack Mine water quality model has been updated in support of an application to increase the mine's production rate to 4950 tpd. The updated model applies the 4950 tpd mine plan and incorporates an updated groundwater model, an updated water balance model, new geochemical data sets, and operational data acquired through the mine's various monitoring programs.

The overall approach for modelling water quality follows what has been presented in previous model reports (*e.g.*, Lorax 2020a), but applies recent monitoring and experimental data sets where applicable. Notable updates for the 2023 water quality model include:

- An updated groundwater model which incorporates the 4950 tpd mine plan and recent flow observations (Lorax, 2023a).
- Revision to the site's water balance based on observed flows, changes to the mine plan and updated water management plans (described in Lorax, 2023b).
- Revision to assumptions regarding WRTSF mixing behaviour where a spring turnover event is not included in the model beyond 2019 (Section 2.1.8).
- Application of operational monitoring results to the background source term for parameters where recent data show lower concentrations than baseline data sets (Section 3.1).
- Refinement of water treatment plant removal efficiencies based on operational data sets (Section 3.5).
- Revision to the STP effluent term using operational water quality data sets for all parameters (Section 3.7).

The water quality model results and the associated effects assessment are summarized as follows:

- Based on predicted water quality for operation, closure and post-closure phases, parameters of potential concern were identifed as having maximum Base Case modelled concentrations above 80% of relevant benchmarks (either discharge limits or FWAL guidelines). POPCs identified were ammonia, nitrite, nitrate, sulfate, aluminum, arsenic, copper, and selenium. These POPCs were assessed for potential to cause toxicity to aquatic life in the receiving environment.
- The maximum Base Case prediction for ammonia at BJ 3.10 (3.53 mg-N/L) occurs during the operations phase, with loads primarily attributed to the deposition of

waste rock in the WRTSF. Maximum Base Case predictions at BJ 2.62 (3.21 mg-N/L) occur during closure when flushing loads are released from the underground mine upon flooding. Ammonia is not predicted to go above the current discharge limit of 4.0 mg-N/L at any point during LOM.

- The maximum Base Case prediction for nitrite at BJ 3.10 (0.13 mg-N/L) is below the current discharge limit of 0.24 mg/L. Base Case predictions at BJ 2.62 go up to the current discharge limit (0.24 mg-N/L) during closure when flushing loads are released from the underground mine upon flooding. This flushing peak is of short duration (one month) and will be managed as per the Underground Water Quality at Closure Adaptive Management Plan (Pretium, 2020e) to ensure that concentrations in the receiving environment remain below the discharge limit.
- The maximum Base Case predictions for nitrate at BJ 3.10 (15.2 mg-N/L) and BJ 2.62 (13.8 mg-N/L) occur during the operations phase, with loads attributed to blasting residues associated with waste rock deposited in the WRTSF. Nitrate levels measured in Brucejack Creek during operations have been well represented by the Base Case model, and the updated model predicts that nitrate will go above the current discharge limit of 11.5 mg-N/L. An effects assessment was carried out on the modelled nitrate concentrations, supported by site-specific toxicity testing. The effect assessment concluded that there is low risk of eutrophication and low risk of toxicity to aquatic life in Brucejack Creek, for both the Base Case and Upper Case models.
- The maximum Base Case prediction for sulfate at BJ 3.10 (114 mg/L) occurs during the operations phase, with loads dominantly attributed to tailings effluent discharged to the WRTSF. Maximum Base Case predictions at BJ 2.62 (197 mg/L) occur during closure when flushing loads are released from the underground mine upon flooding. Base Case modelled sulfate concentrations are below the BC FWAL guideline applicable to the modelled hardness levels; therefore, toxicity to aquatic life in the receiving environment is unlikely.
- The maximum Base Case predictions for D-Al at BJ 3.10 (0.062 mg/L) and BJ 2.62 (0.057 mg/L) occur during the operations phase, with mine-related loads dominantly attributed to the deposition of waste rock in the WRTSF. Base Case D-Al concentrations go above the long-term BC FWAL guideline of 0.05 mg/L, but the model is considered to be overly conservative with respect to D-Al since it does not account for solubility-controlled precipitation reactions. Monitoring of D-Al at BJ 3.10 has shown that measured concentrations have been lower than Base Case predictions, which supports the conclusion that solubility-controlled

precipitation reactions are occuring and concentrations above the BC FWAL guideline are not anticipated.

- The maximum Base Case prediction for T-As at BJ 3.10 (0.014 mg/L) occurs early in the operations phase, with loads dominantly attributed to waste rock placed in the WRTSF. Maximum Base Case predictions at BJ 2.62 (0.012 mg /L) also occur during operations. A concentration peak at BJ 2.62 of 0.011 mg/L is predicted during closure when flushing loads are released from the underground mine upon flooding. T-As concentrations at BJ 3.10 and BJ 2.62 are predicted to exceed the mine's current discharge limit of 0.010 mg/L during operations, as well as at BJ 2.62 during closure. An effects assessment, which included the results of three separate site-specific toxicity tests, concluded that there is low risk of toxicity to aquatic life in the receiving environment, for both the Base Case and Upper case models.
- The maximum Base Case prediction for D-Cu at BJ 3.10 (0.00042 mg/L) occurs at the end of the operations phase, with loads dominantly attributed to background runoff and waste rock deposited in the WRTSF. Maximum Base Case D-Cu predictions at BJ 2.62 (0.0017 mg/L) occur during closure when flushing loads are released from the underground mine upon flooding. Predicted D-Cu concentrations at BJ 3.10 and BJ 2.62 are consistenly greater than the BC FWAL long-term guideline but remain below the BC FWAL short-term guideline. An effects assessment, which included results of site-specific toxicity testing of four species, concluded that there is low risk of toxicity to aquatic life in the receiving environment for both the Base Case and Upper Case models.
- The maximum Base Case prediction for T-Se at BJ 3.10 (0.0021 mg/L) occurs during the operations phase, with loads dominantly attributed to tailings effluent and waste rock placed in the WRTSF. Maximum Base Case T-Se predictions at BJ 2.62 (0.0037 mg/L) occur during closure when flushing loads are released from the underground mine upon flooding. T-Se concentrations at both BJ 3.10 and BJ 2.62 are predicted to go above the BC FWAL long-term guideline of 0.002 mg/L. An effects assessment concluded that there is low risk of toxicity to aquatic life in the receiving environment, including waterbirds, from both the Base Case and Upper Case models.

Water quality monitoring results have shown that water has and is continuing to be managed to meet the requirements of PE-107835, including effluent quality limits. Concentrations of metals and other parameters monitored at the outlet of the WRTSF have been below the current limits in PE-107835 and/or below BC FWAL guidelines. The

4950 tpd Base Case water quality model predicts that certain parameters (nitrite, nitrate, T-As, D-Cu, and T-Se) will be equal to or greater than the mine's current discharge limits or BC FWAL guidelines. However, based on the effects assessment results presented in Section 5, the anticipated concentrations of these parameters are unlikely to cause toxicity to aquatic life in Brucejack Creek.

Efforts to reduce model uncertainty and advance closure planning will be on-going throughout mine operations. Model uncertainties will be addressed through continued assessment of data collected through the environmental monitoring programs and specific analytical programs designed to target key areas of uncertainty. The environmental management plans in effect outline sampling recommendations, management triggers, and corrective actions that are designed to minimize potential adverse effects to water quality. These include monitoring programs developed for surface water, groundwater, WTP influent and effluent, STP discharge, mine site contact water, waste rock, NPAG quarry rock, tailings, paste backfill, and underground mine water. The results will be evaluated to identify potential environmental issues, to improve understanding of site-specific geochemical behaviour, and to verify the site-wide water quality model.

Recommendations to reduce model uncertainty that go beyond work described in environmental management plans are as follows:

- Saturated column tests on WTP sludge if the chemistry of mine water changes significantly or if modifications are made to the water treatment process.
- Kinetic tests on tailings if changes are made to the milling process such that the chemistry of the tailings changes significantly.
- An assessment of water treatment plant removal efficiencies using the sodium sulfide treatment process to refine contigency plans.

Notes:
BC FWAL = BC water quality guidelines for protection of freshwater aquatic life.
Concentrations that greater than long-term guidelines are shaded green & **bold font**.
Concentrations that greater than short-term guidelines are shaded blue & **bold font**.
Concentrations that exceed an effluent discharge limit are shaded **grey & bold font**.
Hardness dependent guidelines calculated using the baseline median hardness of 28 mg/L as $CaCO_3$.
Ammonia guidelines calculated using a pH of 8.0 and temperature of 15°C.
Copper guidelines calculated using the BC biotic ligand model. Inputs to the model were the 2019 annual averages measured at BJ 3.10 of pH 7.9, DOC 0.5 mg/L, Alkalinity 52 mg/L, Ca 24 mg/L, Mg 1.2 mg/L, Na 22 mg/L, K 7.7 mg/L, SO_4 46.5 mg/L, and Cl 1.6 mg/L. A summer temperature of 10 °C was used. The default of 10% of DOC present as humic acid was used.
Chromium guideline is for Cr(VI).
NP=none proposed.
NA=not applicable because the WQG is superseded by the discharge limit.

Appendix A-1: BJ 3.10 Results

Appendix A-1-1: Base BJ 3.10 Base Case Water Quality Predictions

Notes:
BC FWAL = BC water quality guidelines for protection of freshwater aquatic life.
Concentrations that greater than long-term guidelines are shaded green & **bold font**.
Concentrations that greater than short-term guidelines are shaded blue & **bold font**.
Concentrations that exceed an effluent discharge limit are shaded **grey & bold font**.
Hardness dependent guidelines calculated using the baseline median hardness of 28 mg/L as $CaCO_3$.
Ammonia guidelines calculated using a pH of 8.0 and temperature of 15°C.
Copper guidelines calculated using the BC biotic ligand model. Inputs to the model were the 2019 annual averages measured at BJ 3.10 of pH 7.9, DOC 0.5 mg/L, Alkalinity 52 mg/L, Ca 24 mg/L, Mg 1.2 mg/L, Na 22 mg/L, K 7.7 mg/L, SO_4 46.5 mg/L, and Cl 1.6 mg/L. A summer temperature of 10 °C was used. The default of 10% of DOC present as humic acid was used.
Chromium guideline is for Cr(VI).
NP=none proposed.
NA=not applicable because the WQG is superseded by the discharge limit.

Appendix A-1: BJ 3.10 Results

Appendix A-1-1: Base BJ 3.10 Base Case Water Quality Predictions

Notes:
BC FWAL = BC water quality guidelines for protection of freshwater aquatic life.
Concentrations that greater than long-term guidelines are shaded green & **bold font**.
Concentrations that greater than short-term guidelines are shaded blue & **bold font**.
Concentrations that exceed an effluent discharge limit are shaded **grey & bold font**.
Hardness dependent guidelines calculated using the baseline median hardness of 28 mg/L as $CaCO_3$.
Ammonia guidelines calculated using a pH of 8.0 and temperature of 15°C.
Copper guidelines calculated using the BC biotic ligand model. Inputs to the model were the 2019 annual averages measured at BJ 3.10 of pH 7.9, DOC 0.5 mg/L, Alkalinity 52 mg/L, Ca 24 mg/L, Mg 1.2 mg/L, Na 22 mg/L, K 7.7 mg/L, SO_4 46.5 mg/L, and Cl 1.6 mg/L. A summer temperature of 10 °C was used. The default of 10% of DOC present as humic acid was used.
Chromium guideline is for Cr(VI).
NP=none proposed.
NA=not applicable because the WQG is superseded by the discharge limit.

Appendix A-1: BJ 3.10

Appendix A-1-2: Upper Case BJ 3.10 Upper Case Water Quality Predictions

Notes:
BC FWAL = BC water quality guidelines for protection of freshwater aquatic life.
Concentrations that greater than long-term guidelines are shown in ***bold italic*** font.
Concentrations that greater than short-term guidelines are shown in **bold** font.
Concentrations that exceed an effluent discharge limit are shaded in **grey bold font**.
Hardness dependent guidelines calculated using the baseline median hardness of 28 mg/L as $CaCO_3$.
Ammonia guidelines calculated using a pH of 8.0 and temperature of 15°C.
Copper guidelines calculated using the BC biotic ligand model. Inputs to the model were the 2019 annual averages measured at BJ 3.10 of pH 7.9, DOC 0.5 mg/L, Alkalinity 52 mg/L, Ca 24 mg/L, Mg 1.2 mg/L, Na 22 mg/L, K 7.7 mg/L, SO_4 46.5 mg/L, and Cl 1.6 mg/L. A summer temperature of 10 °C was used. The default of 10% of DOC present as humic acid was used.
Chromium guideline is for Cr(VI).
NP=none proposed.
NA=not applicable because the WQG is superseded by the discharge limit.

Notes:
BC FWAL = BC water quality guidelines for protection of freshwater aquatic life.
Concentrations that greater than long-term guidelines are shown in ***bold italic*** font.
Concentrations that greater than short-term guidelines are shown in **bold** font.
Concentrations that exceed an effluent discharge limit are shaded in **grey bold font**.
Hardness dependent guidelines calculated using the baseline median hardness of 28 mg/L as $CaCO_3$.
Ammonia guidelines calculated using a pH of 8.0 and temperature of 15°C.
Copper guidelines calculated using the BC biotic ligand model. Inputs to the model were the 2019 annual averages measured at BJ 3.10 of pH 7.9, DOC 0.5 mg/L, Alkalinity 52 mg/L, Ca 24 mg/L, Mg 1.2 mg/L, Na 22 mg/L, K 7.7 mg/L, SO_4 46.5 mg/L, and Cl 1.6 mg/L. A summer temperature of 10 °C was used. The default of 10% of DOC present as humic acid was used.
Chromium guideline is for Cr(VI).
NP=none proposed.
NA=not applicable because the WQG is superseded by the discharge limit.

Notes:
BC FWAL = BC water quality guidelines for protection of freshwater aquatic life.
Concentrations that greater than long-term guidelines are shown in ***bold italic*** font.
Concentrations that greater than short-term guidelines are shown in **bold** font.
Concentrations that exceed an effluent discharge limit are shaded in **grey bold font**.
Hardness dependent guidelines calculated using the baseline median hardness of 28 mg/L as $CaCO_3$.
Ammonia guidelines calculated using a pH of 8.0 and temperature of 15°C.
Copper guidelines calculated using the BC biotic ligand model. Inputs to the model were the 2019 annual averages measured at BJ 3.10 of pH 7.9, DOC 0.5 mg/L, Alkalinity 52 mg/L, Ca 24 mg/L, Mg 1.2 mg/L, Na 22 mg/L, K 7.7 mg/L, SO_4 46.5 mg/L, and Cl 1.6 mg/L. A summer temperature of 10 °C was used. The default of 10% of DOC present as humic acid was used.
Chromium guideline is for Cr(VI).
NP=none proposed.
NA=not applicable because the WQG is superseded by the discharge limit.

Notes:
BC FWAL = BC water quality guidelines for protection of freshwater aquatic life.
Concentrations that greater than long-term guidelines are shown in ***bold italic*** font.
Concentrations that greater than short-term guidelines are shown in **bold** font.
Concentrations that exceed an effluent discharge limit are shaded in **grey bold font**.
Hardness dependent guidelines calculated using the baseline median hardness of 28 mg/L as $CaCO^3$.
Ammonia guidelines calculated using a pH of 8.0 and temperature of 15°C.
Copper guidelines calculated using the BC biotic ligand model. Inputs to the model were the 2019 annual averages measured at BJ 3.10 of pH 7.9, DOC 0.5 mg/L, Alkalinity 52 mg/L, Ca 24 mg/L, Mg 1.2 mg/L, Na 22 mg/L, K 7.7 mg/L, SO^4 46.5 mg/L, and Cl 1.6 mg/L. A summer temperature of 10 °C was used. The default of 10% of DOC present as humic acid was used.
Chromium guideline is for Cr(VI).
NP=none proposed.
NA=not applicable because the WQG is superseded by the discharge limit.

Notes:
BC FWAL = BC water quality guidelines for protection of freshwater aquatic life.
Concentrations that greater than long-term guidelines are shown in ***bold italic*** font.
Concentrations that greater than short-term guidelines are shown in **bold** font.
Concentrations that exceed an effluent discharge limit are shaded in **grey bold font**.
Hardness dependent guidelines calculated using the baseline median hardness of 28 mg/L as $CaCO_3$.
Ammonia guidelines calculated using a pH of 8.0 and temperature of 15°C.
Copper guidelines calculated using the BC biotic ligand model. Inputs to the model were the 2019 annual averages measured at BJ 3.10 of pH 7.9, DOC 0.5 mg/L, Alkalinity 52 mg/L, Ca 24 mg/L, Mg 1.2 mg/L, Na 22 mg/L, K 7.7 mg/L, SO_4 46.5 mg/L, and Cl 1.6 mg/L. A summer temperature of 10 °C was used. The default of 10% of DOC present as humic acid was used.
Chromium guideline is for Cr(VI).
NP=none proposed.
NA=not applicable because the WQG is superseded by the discharge limit.

Notes:
BC FWAL = BC water quality guidelines for protection of freshwater aquatic life.
Concentrations that greater than long-term guidelines are shown in ***bold italic*** font.
Concentrations that greater than short-term guidelines are shown in **bold** font.
Concentrations that exceed an effluent discharge limit are shaded in **grey bold font**.
Hardness dependent guidelines calculated using the baseline median hardness of 28 mg/L as $CaCO_3$.
Ammonia guidelines calculated using a pH of 8.0 and temperature of 15°C.
Copper guidelines calculated using the BC biotic ligand model. Inputs to the model were the 2019 annual averages measured at BJ 3.10 of pH 7.9, DOC 0.5 mg/L, Alkalinity 52 mg/L, Ca 24 mg/L, Mg 1.2 mg/L, Na 22 mg/L, K 7.7 mg/L, SO_4 46.5 mg/L, and Cl 1.6 mg/L. A summer temperature of 10 °C was used. The default of 10% of DOC present as humic acid was used.
Chromium guideline is for Cr(VI).
NP=none proposed.
NA=not applicable because the WQG is superseded by the discharge limit.

Notes:
BC FWAL = BC water quality guidelines for protection of freshwater aquatic life.
Concentrations that greater than long-term guidelines are shown in ***bold italic*** font.
Concentrations that greater than short-term guidelines are shown in **bold** font.
Concentrations that exceed an effluent discharge limit are shaded in **grey bold font**.
Hardness dependent guidelines calculated using the baseline median hardness of 28 mg/L as $CaCO^3$.
Ammonia guidelines calculated using a pH of 8.0 and temperature of 15°C.
Copper guidelines calculated using the BC biotic ligand model. Inputs to the model were the 2019 annual averages measured at BJ 3.10 of pH 7.9, DOC 0.5 mg/L, Alkalinity 52 mg/L, Ca 24 mg/L, Mg 1.2 mg/L, Na 22 mg/L, K 7.7 mg/L, SO^4 46.5 mg/L, and Cl 1.6 mg/L. A summer temperature of 10 °C was used. The default of 10% of DOC present as humic acid was used.
Chromium guideline is for Cr(VI).
NP=none proposed.
NA=not applicable because the WQG is superseded by the discharge limit.

Notes:
BC FWAL = BC water quality guidelines for protection of freshwater aquatic life.
Concentrations that greater than long-term guidelines are shown in ***bold italic*** font.
Concentrations that greater than short-term guidelines are shown in **bold** font.
Concentrations that exceed an effluent discharge limit are shaded in **grey bold font**.
Hardness dependent guidelines calculated using the baseline median hardness of 28 mg/L as $CaCO_3$.
Ammonia guidelines calculated using a pH of 8.0 and temperature of 15°C.
Copper guidelines calculated using the BC biotic ligand model. Inputs to the model were the 2019 annual averages measured at BJ 3.10 of pH 7.9, DOC 0.5 mg/L, Alkalinity 52 mg/L, Ca 24 mg/L, Mg 1.2 mg/L, Na 22 mg/L, K 7.7 mg/L, SO_4 46.5 mg/L, and Cl 1.6 mg/L. A summer temperature of 10 °C was used. The default of 10% of DOC present as humic acid was used.
Chromium guideline is for Cr(VI).
NP=none proposed.
NA=not applicable because the WQG is superseded by the discharge limit.

Notes:
BC FWAL = BC water quality guidelines for protection of freshwater aquatic life.
Concentrations that greater than long-term guidelines are shown in ***bold italic*** font.
Concentrations that greater than short-term guidelines are shown in **bold** font.
Concentrations that exceed an effluent discharge limit are shaded in **grey bold font**.
Hardness dependent guidelines calculated using the baseline median hardness of 28 mg/L as $CaCO^3$.
Ammonia guidelines calculated using a pH of 8.0 and temperature of 15°C.
Copper guidelines calculated using the BC biotic ligand model. Inputs to the model were the 2019 annual averages measured at BJ 3.10 of pH 7.9, DOC 0.5 mg/L, Alkalinity 52 mg/L, Ca 24 mg/L, Mg 1.2 mg/L, Na 22 mg/L, K 7.7 mg/L, SO^4 46.5 mg/L, and Cl 1.6 mg/L. A summer temperature of 10 °C was used. The default of 10% of DOC present as humic acid was used.
Chromium guideline is for Cr(VI).
NP=none proposed.
NA=not applicable because the WQG is superseded by the discharge limit.

Memorandum

Date: January 18, 2017

From: ERM Consultants Canada Ltd.

Subject: **Streamflow Ratios Supporting Dilution Analyses in Brucejack Creek and Sulphurets Creek**

1. INTRODUCTION

The geographic extent of potential effects from elevated nitrate and nitrite are defined as waters (i.e. receiving environment) with predicted concentrations greater than the British Columbia Water Quality Guidelines (BCWQGs) for the protection of aquatic life. Brucejack Creek at BJ 3.10 is predicted to have concentrations of nitrate and nitrite greater than their respective BCWQGs. Brucejack Creek flows into Sulphurets Creek at SC0, where nitrate and nitrite concentrations are below the BCWQGs (Table 1).

Table 1. Dilution required to equal BC Water Quality Guidelines in Sulphurets Creek

Parameter	Model case	BJ 3.10 (mg-N/L)	SC0 (mg-N/L)	BCWQG (mg-N/L)	Required Dilution
Nitrate	Expected Case	5.1	0.05	3.0	1:1
	Upper Case	11.5	0.05	3.0	3:1
Nitrite	Expected Case	0.11	0.001	0.02	5:1
	Upper Case	0.24	0.001	0.02	12:1

The maximum required dilution is 12:1 Brucejack Creek at BJ 3.10 to Sulphurets Creek at SC0 (to produce NO_2 <0.02 mg-N/L). This memorandum provides an update to the assessment of streamflow ratios along Sulphurets Creek, and includes the results of previous studies, as well as a description of the methodology used to assess ratios used in this update.

2. BACKGROUND

ERM (2014) provided streamflow ratio estimates that support a dilution analysis of flows from Brucejack Creek into Sulphurets Creek. Three approaches were used to estimate streamflow ratio:

a) *use of drainage area as a surrogate for streamflow ratio;*

b) *analysis of data collected during the baseline monitoring program (open water season only); and*

c) *regional hydrologic analysis.*

The ratio of streamflow at Sulphurets Lake Outflow (at hydrometric station SL-H1) to streamflow at Brucejack Creek (at hydrometric station BJ 1.74, also known as BJL-H1a), using *Methods a*, *b*, and *c*, were 8.8, 14.6, and 9.7, respectively (ERM 2014). Based on these results, ERM (2014) concluded that the drainage area approach (i.e., *Method a*) provides the most conservative estimates for streamflow ratios, with 8:1 being the ratio selected for the Sulphurets Lake Inflow compared to Brucejack Creek at BJ 1.74. This conclusion assumes that drainage area ratios (*Method a*) may be used as a surrogate for streamflow ratios, which may further be used as a surrogate for dilution ratios.

ERM (2016) was completed and superseded ERM (2014) following collection of additional 366 concurrent daily streamflow records (June to September 2013-2015). It was found that additional data did not change ERM (2014) recommendations (ERM 2016). Catchment area ratios consistently provided the most conservative streamflow ratio and so was recommended.

Streamflow ratios, determined from the ratio of measured discharge, is the preferred method (*Method b*), but these results were not chosen in the previous study (*Method a*) due to the limited extent of site record available, and use of open water season data only.

3. 2017 STREAMFLOW RATIOS

ERM has recently completed a detailed hydrologic analysis of the major tributaries of the Sulphurets Valley, which resulted in the development of a series of long-term transposed streamflow records for select hydrometric monitoring stations (Table 2). These records (each 66 years in length) were derived by integrating project hydrometric records, with long-term regional Water Survey of Canada records, using the empirical frequency pairing method described in Butt (2013).

The monthly distribution of average streamflow in Brucejack Creek is different from Sulphurets Creek (Plate 1), and these differences impact streamflow ratios at different times of the year. The highest monthly flows in Brucejack Creek occur during the prominent freshet peak, while for Sulphurets Creek, the highest flows occur during the summer months, in response to melting of large, lower elevation glaciers. Thus, major differences in runoff between Brucejack Creek and Sulphurets Creek result from the presence, size, orientation and elevation of glaciers, and that the catchment area ratio (*Method a*) did not reflect these differences accurately.

Plate 1. Monthly Distribution of Streamflow

The long-term transposed streamflow records were used to more accurately determine the ratios of streamflow at Brucejack Creek (at BJ 3.10), to various nodes along Sulphurets Creek using average monthly flows (Table 3). The process was straight forward, though some nodes were not located at specific monitoring stations, and thus minor spatial extrapolation of runoff was necessary. Extrapolation was achieved by assuming that flows downstream of monitoring stations were a function of non-glaciated runoff conditions, which was calculated for each node as proportional runoff, based on a mass balance of flows in the Sulphurets Valley.

Table 2. Hydrometric Stations with Long-Term Transposed Streamflow Records

#	Node	Description	Easting	Northing	Catchment (km^2)
1	BJ 1.74	Brucejack Creek, 1.74 km upstream of Confluence	425737	6259076	8.5
2	SL-H2	Sulphurets Creek, downstream of Sulphurets Lake	419769	6261350	75.6
3	TMC-H1	Ted Morris Creek	416883	6259497	56.6
4	MC-H2	Mitchell Creek, immediately upstream of Confluence	416740	6262837	87.9
5	GC-H1	Gingras Creek, immediately upstream of Confluence	416277	6262834	9.8
6	SC-H1	Sulphurets Creek, at the Mouth	408256	6261490	289.4

Table 3. Sulphurets Valley Dilution Ratio Node Details

Node	Alias	Easting	Northing	Catchment (km^2)	Catchment Ratio[1]
Brucejack Lk (BJ 3.10)	BJ 3.10	427030	6258895	6.7	1
Sulphurets Creek d/s Sulphurets Lk	SL-H2	419769	6261350	75.6	11
Sulphurets Creek, u/s Ted Morris Crk	SC-TMU	417520	6261990	86.8	13
Sulphurets Creek, d/s Ted Morris Crk	SC-TMD	417285	6262111	149.8	22
Sulphurets Creek, u/s Mitchell Crk	SC-MCU	416354	6262487	151.5	23

Notes:

1. *Catchment Ratio provided as a reference, using the methodology described in ERM (2014), Method "a"*

Previous studies were based on discharge data from BJ 1.74. Therefore, streamflow for BJ 1.74 was transposed to BJ 3.10 by catchment area proration. Long-term streamflow were then determined at other nodes by using the long-term streamflow records from nearby monitoring stations, and integrating where necessary to provide reasonable estimates of discharge at the specific node.

- SL-H2 used the long-term transposed records of the monitoring station SL-H2,
- SC-TMU used SL-H2, with the addition of runoff from the non-glaciated catchment area downstream of the monitoring station SL-H2,
- SC-TMD used SC-TMU, with the addition of runoff from the monitoring station TMC-H1, and the addition of runoff from the non-glaciated Ted Morris Valley catchment downstream of TMC-H1,
- SC-MCU used SC-TMD, with the addition of runoff from the non-glaciated catchment Sulphurets Valley catchment area downstream of SC-TMD.

Monthly streamflow is included in Table 4, and monthly ratios are included in Table 5 and Plate 2 (the dashed line represents the 12:1 discharge ratio).

Table 4. Average Monthly Streamflow (m^3/s) at nodes along Sulphurets Valley

Node	JAN	FEB	MAR	APR	MAY	JUN	JUL	AUG	SEP	OCT	NOV	DEC
BJ 3.10	0.06	0.05	0.05	0.10	0.55	1.32	1.1	0.86	0.62	0.43	0.20	0.10

SC-MCU	25	25	25	25	16	17	34	37	32	28	19	17

Plate 1. Streamflow Ratios at Nodes Along Sulphurets Valley

4. CLOSING

ERM used long-term streamflow estimates to derive estimates of streamflow ratios at nodes along the Sulphurets Valley. It was found that the required 12:1 streamflow ratio (compared to streamflow in Brucejack Creek at BJ 3.10) will be comfortably achieved in all months, immediately below the Ted Morris confluence, at SC-TMD.

Should you have any questions or concerns, please do not hesitate to contact ERM.

This report has been prepared by Nautilus Environmental Company Inc. based on data and/or samples provided by our client and the results of this study are for their sole benefit. Any reliance on the data by a third party is at the sole and exclusive risk of that party. The results presented here relate only to the samples tested.

SUMMARY

Sample Information and Test Type

Sample ID	Nitrate in laboratory water Nitrate in site water (BJ-3.10)
Sample collection date	December 7, 2021
Sample receipt date	December 9, 2021
Sample receipt temperature	4.1 – 8.6°C
Test types	10-d *Chironomus dilutus* survival and growth *Ceriodaphnia dubia* survival and reproduction

Summary of Results

Endpoint	**mg/L NO_3-N (95% CL)**	
	Laboratory Water	Site Water (BJ-3.10)
Chironomus dilutus		
Survival LC50	>280	150.7 (130.7 – 173.9)
Dry weight IC20	24.2 (9.0 – 55.0)	179.6 (2.9 – N/A)
Dry weight IC50	>280	>303
Ceriodaphnia dubia		
Survival LC50	>286.5	>303
Reproduction IC20	120.0 (82.5 – 150.4)	54.1 (46.0 – 61.1)
Reproduction IC50	187.5 (176.9 – 197.3)	88.5 (77.8 – 98.8)

LC = Lethal Concentration, IC = Inhibition Concentration, CL = Confidence Limits, N/A = Not Available

1.0 INTRODUCTION

Nautilus Environmental Company Inc. conducted toxicity tests using *Chironomus dilutus* and *Ceriodaphnia dubia* on behalf of Pretivm Resources Inc. to evaluate the effects nitrate on survival and growth or reproduction. Tests were conducted concurrently at the Nautilus Environmental laboratory in Burnaby, BC, using site water identified as BJ-3.10 and the laboratory control waters with a hardness of 100 mg/L. The purpose of the tests was to determine whether nitrate exhibited a different degree of toxicity in site water compared to laboratory water.

The results of the toxicity tests are presented in this report. Copies of laboratory data sheets and statistical analyses for the tests are provided in Appendices A and B. The results of analytical chemistry are provided in Appendix C. The chain-of-custody form is provided in Appendix D.

2.0 METHODS

The site water was collected by Pretivm Resources Inc. staff on December 7, 2021 in five 20-L carboys and delivered to the Nautilus Environmental laboratory in Burnaby, BC on December 9, 2021. The sample was received at a temperature ranging between 4.1 and 8.6°C. Methods for the toxicity tests are summarized in Tables 1 and 2. Testing was conducted according to procedures described by Environment Canada (1997 and 2007). A stock solution of 25 g/L NO_3-N was used for preparation of test solutions. In the case of the chironomid test, the method was modified to perform the exposure with a minimal amount of control sand in the test containers to provide substrate for the test organisms.

Subsamples of nitrate were collected in plastic HDPE bottles for each concentration at test initiation from freshly prepared solutions and at termination from the test vessels. Laboratory control water and site water were also analyzed for hardness, total dissolved and suspended solids, major anions, nutrients and total and dissolved metals. Subsamples were analyzed by ALS Environmental (Burnaby, BC); results are provided in Appendix C.

Statistical analyses for the tests were performed using CETIS (Tidepool Scientific Software, 2013) and were conducted using averaged measured concentrations of nitrate from test initiation and termination.

Table 1. Summary of test conditions: 10-d *Chironomus dilutus* water-only survival and growth test.

Test species	*Chironomus dilutus*
Organism source	Aquatic BioSystems, Fort Collins, CO
Organism age	Third instar
Test type	Static-renewal
Test duration	10 days
Test vessel	375-mL glass container
Test volume	275 mL of test solution and ~2 mm of control sand
Test concentrations	Seven concentrations, plus laboratory/site control
Test replicates	5 per sample
Number of organisms	10 per replicate
Control/dilution water	Moderately hard synthetic water prepared using dechlorinated municipal tapwater
Test solution renewal	Three times a week on non-consecutive days
Test temperature	23 ± 1°C
Feeding	6 mg of Tetramin per replicate daily
Light intensity	500 to 1000 lux at water surface
Photoperiod	16 hours light/8 hours dark
Aeration	None, until day 4 of test
Test measurements	Temperature, dissolved oxygen, pH and conductivity of overlying water measured daily; hardness, alkalinity and total ammonia of overlying water measured at test initiation and termination
Test protocol	Environment Canada (1997), EPS 1/RM/32 (modified)
Statistical software	CETIS Version 1.9.4
Test endpoints	Survival and dry weight
Test acceptability criteria for controls	≥70% survival; ≥0.6 mg/worm dry weight
Reference toxicant	Potassium chloride (KCl)

Table 2. Summary of test conditions: *Ceriodaphnia dubia* survival and reproduction test.

Test species	*Ceriodaphnia dubia*
Organism source	In-house culture
Organism age	<24 hour old neonates, produced within a 12 hour window
Test type	Static-renewal
Test duration	7 ± 1 day
Test vessel	20-mL glass test tube
Test volume	15 mL
Test solution depth	10 cm
Test concentrations	Seven concentrations, plus laboratory/site control
Test replicates	10 per treatment
Number of organisms	1 per replicate
Control/dilution water	20% Perrier water and 80% deionized water + 5 µg/L Se and 2 µg/L vitamin B12
Test solution renewal	Daily (100% renewal)
Test temperature	25 ± 1°C
Feeding	Daily with *Pseudokirchneriella subcapitata* and TCC[1] (3:1 ratio)
Light intensity	100 to 600 lux at water surface
Photoperiod	16 hours light / 8 hours dark
Aeration	None
Test measurements	Temperature, dissolved oxygen, pH and conductivity measured daily; hardness and alkalinity of undiluted sample measured at test initiation; survival and reproduction checked daily
Test protocol	Environment Canada (2007), EPS 1/RM/21
Statistical software	CETIS Version 1.9.4
Test endpoints	Survival and reproduction
Test acceptability criteria for controls	≥80% survival; ≥15 young per surviving control producing three broods; ≥60% of controls producing three or more broods; no ephippia present
Reference toxicant	Sodium chloride (NaCl)

[1] TCC = Trout chow and Cerophyl

3.0 RESULTS

Measured concentrations of nitrate were in good agreement with the targeted values (Tables 3 to 6) and were generally within 10% of nominal values (after accounting for the background level of nitrate in sample BJ-3.10). The measured values after 24-48 hours of exposure were also generally within 10% of the values measured at test initiation, indicating that the test solutions were stable in between solution renewals.

Results of the *C. dilutus* survival and growth tests are summarized in Tables 3 and 4. The LC50 was >280 mg/L NO_3-N in the laboratory water test and was 150.7 mg/L NO_3-N in site water. Adverse effects were observed on the growth of *C. dilutus*, with IC20 values of 24.2 and 179.6 mg/L NO_3-N in laboratory and site water, respectively.

Results of the *C. dubia* survival and reproduction tests are summarized in Tables 5 and 6. No effects were observed on survival in either the laboratory or site waters, resulting in LC50 values that were greater than the highest test concentrations. The IC20 for reproduction was 120.0 and 54.1 mg/L NO_3 in laboratory and site water, respectively. Nitrate exhibited a higher degree of toxicity in site water compared to the laboratory water.

Table 3. Results of the *Chironomus dilutus* survival and growth test conducted in laboratory water.

mg/L NO_3-N		Survival (%) (Mean ± SD)	Dry Weight (mg) (Mean ± SD)
Nominal	**Average measured**

4.0 QA/QC

The health histories of the test organisms used in the exposures were acceptable and met the requirements of the Environment Canada protocols. The tests met all control acceptability criteria and water quality parameters remained within ranges specified in the protocols throughout the tests, with the exception of the freshly prepared dilutions in the *C. dubia* test in site water on Day 3; temperature was recorded at 23°C, which is marginally outside of the required range of 25±1°C. This deviation would not be expected to have affected the results of the test. There were no other deviations from the test methodologies. Uncertainty associated with these tests is best described by the standard deviations around the means or the confidence limits surrounding the point estimates.

Results of the reference toxicant tests conducted during the testing program are summarized in Table 7. Results for the tests fell within the acceptable range for organism performance of mean and two standard deviations, based on historical results obtained by the laboratory with these tests. Thus, the sensitivity of the organisms used in the tests was appropriate.

Table 7. Reference toxicant test results.

Test Species	Endpoint	Historical Mean (2 SD Range)	CV (%)	Test Date
C. dilutus	Survival (LC50): 4.3 g/L KCl	5.4 (3.9 – 7.4) g/L KCl	16	December 10, 2021
C. dubia	Survival (LC50): 2.1 g/L NaCl	2.0 (1.8 – 2.2) g/L NaCl	5	December 21, 2021
	Reproduction (IC50): 1.7 (1.5-1.8) g/L NaCl	1.7 (1.4 – 2.2) g/L NaCl	11	

SD = Standard Deviation, CV = Coefficient of Variation, LC = Lethal Concentration, IC = Inhibition Concentration

Chironomus dilutus Water-only Test Summary Sheet

Client: Lorax/Pretivm
Work Order No.: 212487

Start Date: Dec 10/21
Set up by: KJL/GJW/MDO

Sample Information:

Sample ID: NO_3 in BJ-3.10
Sample Date: Dec 7/21
Date Received: Dec 9/21
Sample Volume: 5 x 20L (4x20L + 1x20L)

Test Organism Information:

Species: *C. dilutus*
Supplier: Aquatic Biosystems, CO
Date received: Dec 10/21
Age or size (Day 0): 3rd in-star

KCl Reference Toxicant Results:

Reference Toxicant ID: CT104
Stock Solution ID: n/a
Date Initiated: Dec 10/21

96-h LC50 (95% CL): 4.3 (0.8-6.5)

96-h LC50 Reference Toxicant Mean and Range: 5.4(3.9-7.4) CV (%): 16%

Test Results:
(measured values)

mg/L NO_3-N	Survival	Dry Weight
LC25 (%v/v) (95% CL)	N/A	—
LC50(%v/v) (95% CL)	150.7 (130.7-173.9)	—
IC25(%v/v) (95% CL)	—	208.5 (52.1 - N/A)
IC50(%v/v) (95% CL)	—	>303

APPENDIX B – *Ceriodaphnia dubia* Toxicity Test Data

Ceriodaphnia dubia Summary Sheet

Client: Lorax / Pretivm
Work Order No.: 212488

Start Date/Time: Dec 10/21 @ 1230L
Set up by: JZL

Sample Information:

Sample ID: NO3 Lab Water
Sample Date: Dec 7/21
Date Received: Dec 9/21
Sample Volume: 5 x 20L
(4 x 20L + 1 x 20L)

Test Validity Criteria:

1) Mean survival of first generation controls is ≥80 %
2) At least 60% of controls have produced three broods within 8 days
3) An average of ≥15 live young produced per surviving female in the control solutions during the first three broods.
4) Invalid if ephippia observed in any control solution at any time.

WQ Ranges:

T (°C) = 25 ± 1; DO (mg/L) = 3.3 to 8.4 ; pH = 6.0 to 8.5

Test Organism Information:

Broodstock No.: BB113021 + BB120221B + BB120321
Age of young (Day 0): <24-h (within 12-h)
Avg No. young in first 3 broods of previous 7 d: 22
Mortality (%) in previous 7 d: 3
Individual female # used ≥8 young on test day: #1,2,4 + #21-23,30,35,36,39,40 + #1,3,4,6-8,10-14,16-20.

NaCl Reference Toxicant Results:

Reference Toxicant ID: Cd 296
Stock Solution ID: 21Na03
Date Initiated: Dec 21/21

7-d LC50 (95% CL): 2.1 (1.5-3.0) g/L NaCL
7-d IC50 (95% CL): 1.7 (1.5-1.8) g/L NaCL

7-d LC50 Reference Toxicant Mean and Historical Range: 2.0 (1.8-2.2) g/L NaCL CV (%): 5%
7-d IC50 Reference Toxicant Mean and Historical Range: 1.7 (1.4-2.2) g/L NaCL CV (%): 11%

Test Results:
(measured values)

mg/L NO_3-N	Survival	Reproduction
LC50 % (v/v) (95% CL)	>286.25	—
IC25 % (v/v) (95% CL)	—	146.6 (110 - 157.4)
IC50 % (v/v) (95% CL)	—	187.5 (176.9 - 197.3)

Ceriodaphnia dubia Summary Sheet

Client: Lorax/Pretivm
Work Order No.: 212488

Start Date/Time: Dec 10/21 @ 1200L
Set up by: JZL

Sample Information:

Sample ID: NO3 Site water
Sample Date: Dec 7/21
Date Received: Dec 9/21
Sample Volume: 5x 20L
(4x20L + 1x20L)

Test Validity Criteria:

1) Mean survival of first generation controls is ≥80 %
2) At least 60% of controls have produced three broods within 8 days
3) An average of ≥15 live young produced per surviving female in the control solutions during the first three broods.
4) Invalid if ephippia observed in any control solution at any time.

WQ Ranges:

T (°C) = 25 ± 1; DO (mg/L) = 3.3 to 8.4 ; pH = 6.0 to 8.5

Test Organism Information:

Broodstock No.: BB113021 + BB120221B + BB120321
Age of young (Day 0): <24-h (within 12-h)
Avg No. young in first 3 broods of previous 7 d: 22
Mortality (%) in previous 7 d: 3
Individual female # used ≥8 young on test day: #1,2,4 + #21-23,30,35,36,39,40 + #1,3,4,6-8,10-14,16-20.

NaCl Reference Toxicant Results:

Reference Toxicant ID: Cd296
Stock Solution ID: 21NaCl3
Date Initiated: Dec 21/21

7-d LC50 (95% CL): 2.1(1.5-3.0) g/L NaCL
7-d IC50 (95% CL): 1.7(1.5-1.8) g/L NaCL

7-d LC50 Reference Toxicant Mean and Historical Range: 2.0(1.8-2.2) g/L NaCL CV (%): 5%
7-d IC50 Reference Toxicant Mean and Historical Range: 1.7(1.4-2.2) g/L NaCL CV (%): 11%

Test Results:
(measured values)

mg/L NO3-N	Survival	Reproduction
LC50 % (v/v) (95% CL)	>303	—
IC25 % (v/v) (95% CL)	—	59.0(50.9-67.8)
IC50 % (v/v) (95% CL)	—	88.5(77.8-98.8)

General Comments

The analytical methods used by ALS are developed using internationally recognized reference methods (where available), such as those published by US EPA, APHA Standard Methods, ASTM, ISO, Environment Canada, BC MOE, and Ontario MOE. Refer to the ALS Quality Control Interpretive report (QCI) for applicable references and methodology summaries. Reference methods may incorporate modifications to improve performance.

Where a reported less than (<) result is higher than the LOR, this may be due to primary sample extract/digestate dilution and/or insufficient sample for analysis.

Where the LOR of a reported result differs from standard LOR, this may be due to high moisture content, insufficient sample (reduced weight employed) or matrix interference.

Please refer to Quality Control Interpretive report (QCI) for information regarding Holding Time compliance.

Key : CAS Number: Chemical Abstracts Services number is a unique identifier assigned to discrete substances
LOR: Limit of Reporting (detection limit).

Unit	*Description*
-	No Unit
µS/cm	Microsiemens per centimetre
mg/L	milligrams per litre
NTU	nephelometric turbidity units
pH units	pH units

<: less than.

>: greater than.

Surrogate: An analyte that is similar in behavior to target analyte(s), but that does not occur naturally in environmental samples. For applicable tests, surrogates are added to samples prior to analysis as a check on recovery.

Test results reported relate only to the samples as received by the laboratory.

UNLESS OTHERWISE STATED on SRN or QCI Report, ALL SAMPLES WERE RECEIVED IN ACCEPTABLE CONDITION.

Qualifiers

Qualifier	*Description*
RRV	*Reported result verified by repeat analysis.*

QUALITY CONTROL INTERPRETIVE REPORT

Work Order	: **VA21C8572**	Page	: 1 of 19
Client	: **Nautilus Environmental Company Inc.**	Laboratory	: Vancouver - Environmental
Contact	: Mikayla Oldach	Account Manager	: Emmanuel Mariano
Address	: 8664 Commerce Court Imperial Square Lake City Burnaby BC Canada V5A 4N7	Address	: 8081 Lougheed Highway Burnaby, British Columbia Canada V5A 1W9
Telephone	: ----	Telephone	: +1 604 253 4188
Project	: ----	Date Samples Received	: 21-Dec-2021 16:20
PO	: 2022-0187	Issue Date	: 10-Jan-2022 09:46
C-O-C number	: ----		
Sampler	: ----		
Site	: Tissue, Water and Sediment Testing		
Quote number	: Q69439		
No. of samples received	: 62		
No. of samples analysed	: 62		

This report is automatically generated by the ALS LIMS (Laboratory Information Management System) through evaluation of Quality Control (QC) results and other QA parameters associated with this submission, and is intended to facilitate rapid data validation by auditors or reviewers. The report highlights any exceptions and outliers to ALS Data Quality Objectives, provides holding time details and exceptions, summarizes QC sample frequencies, and lists applicable methodology references and summaries.

Key

Anonymous: Refers to samples which are not part of this work order, but which formed part of the QC process lot.
CAS Number: Chemical Abstracts Services number is a unique identifier assigned to discrete substances.
DQO: Data Quality Objective.
LOR: Limit of Reporting (detection limit).
RPD: Relative Percent Difference.

Summary of Outliers

Outliers : Quality Control Samples

- No Duplicate outliers occur.
- No Matrix Spike outliers occur.
- Method Blank value outliers occur - please see following pages for full details.
- Laboratory Control Sample (LCS) outliers occur - please see following pages for full details.
- No Test sample Surrogate recovery outliers exist.

Outliers: Reference Material (RM) Samples

- No Reference Material (RM) Sample outliers occur.

Outliers : Analysis Holding Time Compliance (Breaches)

- Analysis Holding Time Outliers exist - please see following pages for full details.

Outliers : Frequency of Quality Control Samples

- Quality Control Sample Frequency Outliers occur - please see following pages for full details.

Outliers : Quality Control Samples

Duplicates, Method Blanks, Laboratory Control Samples and Matrix Spikes

Matrix: **Water**

Analyte Group	Laboratory sample ID	Client/Ref Sample ID	Analyte	CAS Number	Method	Result	Limits	Comment
Method Blank (MB) Values								
Anions and Nutrients	QC-377104-001	----	nitrate (as N)	14797-55-8	E235.NO3-L	0.0052 mg/L B	0.005 mg/L	Blank result exceeds permitted value
Anions and Nutrients	QC-377286-001	----	nitrate (as N)	14797-55-8	E235.NO3-L	0.0144 mg/L B	0.005 mg/L	Blank result exceeds permitted value
Total Metals	QC-378469-001	----	arsenic, total	7440-38-2	E468	0.000058 mg/L B	0.00005 mg/L	Blank result exceeds permitted value
Total Metals	QC-378469-001	----	zinc, total	7440-66-6	E468	0.0194 mg/L B	0.003 mg/L	Blank result exceeds permitted value

Result Qualifiers

Qualifier	*Description*
B	*Method Blank exceeds ALS DQO. Associated sample results which are < Limit of Reporting or > 5 times blank level are considered reliable.*

Laboratory Control Sample (LCS) Recoveries								
Dissolved Metals	QC-378611-002	----	sulfur, dissolved	7704-34-9	E469	79.4 % MES	80.0-120%	Recovery less than lower control limit

Result Qualifiers

Qualifier	*Description*
MES	*Data Quality Objective was marginally exceeded (by < 10% absolute) for < 10% of analytes in a Multi-Element Scan / Multi-Parameter Scan (considered acceptable as per OMOE & CCME).*

Analysis Holding Time Compliance

This report summarizes extraction / preparation and analysis times and compares each with ALS recommended holding times, which are selected to meet known provincial and /or federal requirements. In the absence of regulatory hold times, ALS establishes recommendations based on guidelines published by organizations such as CCME, US EPA, APHA Standard Methods, ASTM, or Environment Canada (where available). Dates and holding times reported below represent the first dates of extraction or analysis. If subsequent tests or dilutions exceeded holding times, qualifiers are added (refer to COA).

If samples are identified below as having been analyzed or extracted outside of recommended holding times, measurement uncertainties may be increased, and this should be taken into consideration when interpreting results.

Where actual sampling date is not provided on the chain of custody, the date of receipt with time at 00:00 is used for calculation purposes.

Where only the sample date without time is provided on the chain of custody, the sampling date at 00:00 is used for calculation purposes.

Legend & Qualifier Definitions

EHTR-FM: Exceeded ALS recommended hold time prior to sample receipt. Field Measurement recommended

EHTR: Exceeded ALS recommended hold time prior to sample receipt.

EHT: Exceeded ALS recommended hold time prior to analysis.

Rec. HT: ALS recommended hold time (see units).

Quality Control Parameter Frequency Compliance

The following report summarizes the frequency of laboratory QC samples analyzed within the analytical batches (QC lots) in which the submitted samples were processed. The actual frequency should be greater than or equal to the expected frequency.

Matrix: **Water**

Evaluation: ✗ = *QC frequency outside specification*; ✓ = *QC frequency within specification.*

Quality Control Sample Type			Count		Frequency (%)		
Analytical Methods	*Method*	*QC Lot #*	*QC*	*Regular*	*Actual*	*Expected*	*Evaluation*
Laboratory Duplicates (DUP)							
Alkalinity Species by Titration	E290	377708	0	1	0.0	5.0	✗
Ammonia by Fluorescence	E298	378801	1	5	20.0	5.0	✓

Methodology References and Summaries

The analytical methods used by ALS are developed using internationally recognized reference methods (where available), such as those published by US EPA, APHA Standard Methods, ASTM, ISO, Environment Canada, BC MOE, and Ontario MOE. Reference methods may incorporate modifications to improve performance (indicated by "mod").

Analytical Methods	Method / Lab	Matrix	Method Reference	Method Descriptions
Conductivity in Water	E100 Vancouver - Environmental	Water	APHA 2510 (mod)	Conductivity, also known as Electrical Conductivity (EC) or Specific Conductance, is measured by immersion of a conductivity cell with platinum electrodes into a water sample. Conductivity measurements are temperature-compensated to 25°C.
pH by Meter	E108 Vancouver - Environmental	Water	APHA 4500-H (mod)	pH is determined by potentiometric measurement with a pH electrode, and is conducted at ambient laboratory temperature (normally 20 ± 5°C). For high accuracy test results, pH should be measured in the field within the recommended 15 minute hold time.
Turbidity by Nephelometry	E121 Vancouver - Environmental	Water	APHA 2130 B (mod)	Turbidity is measured by the nephelometric method, by measuring the intensity of light scatter under defined conditions.
TSS by Gravimetry	E160-H Vancouver - Environmental	Water	APHA 2540 D (mod)	Total Suspended Solids (TSS) are determined by filtering a sample through a glass fibre filter, following by drying of the filter at 104 ± 1°C, with gravimetric measurement of the filtered solids. Samples containing very high dissolved solid content (i.e. seawaters, brackish waters) may produce a positive bias by this method. Alternate analysis methods are available for these types of samples.
TDS by Gravimetry	E162 Vancouver - Environmental	Water	APHA 2540 C (mod)	Total Dissolved Solids (TDS) are determined by filtering a sample through a glass fibre filter, with evaporation of the filtrate at 180 ± 2°C for 16 hours or to constant weight, with gravimetric measurement of the residue.
Bromide in Water by IC (Low Level)	E235.Br-L Vancouver - Environmental	Water	EPA 300.1 (mod)	Inorganic anions are analyzed by Ion Chromatography with conductivity and/or UV detection.
Chloride in Water by IC	E235.Cl Vancouver - Environmental	Water	EPA 300.1 (mod)	Inorganic anions are analyzed by Ion Chromatography with conductivity and/or UV detection.
Fluoride in Water by IC	E235.F Vancouver - Environmental	Water	EPA 300.1 (mod)	Inorganic anions are analyzed by Ion Chromatography with conductivity and/or UV detection.
Nitrite in Water by IC (Low Level)	E235.NO2-L Vancouver - Environmental	Water	EPA 300.1 (mod)	Inorganic anions are analyzed by Ion Chromatography with conductivity and/or UV detection.
Nitrate in Water by IC (Low Level)	E235.NO3-L Vancouver - Environmental	Water	EPA 300.1 (mod)	Inorganic anions are analyzed by Ion Chromatography with conductivity and/or UV detection.

Analytical Methods	Method / Lab	Matrix	Method Reference	Method Descriptions
Sulfate in Water by IC	E235.SO4 Vancouver - Environmental	Water	EPA 300.1 (mod)	Inorganic anions are analyzed by Ion Chromatography with conductivity and/or UV detection.
Alkalinity Species by Titration	E290 Vancouver - Environmental	Water	APHA 2320 B (mod)	Total alkalinity is determined by potentiometric titration to a pH 4.5 endpoint. Bicarbonate, carbonate and hydroxide alkalinity are calculated from phenolphthalein alkalinity and total alkalinity values.
Ammonia by Fluorescence	E298 Vancouver - Environmental	Water	J. Environ. Monit., 2005, 7, 37-42 (mod)	Ammonia in water is analyzed by flow-injection analysis with fluorescence detection after reaction with orthophthaldialdehyde (OPA).
Total Organic Carbon (Non-Purgeable) by Combustion (Low Level)	E355-L Vancouver - Environmental	Water	APHA 5310 B (mod)	Total Organic Carbon (Non-Purgeable), also known as NPOC (total), is a direct measurement of TOC after an acidified sample has been purged to remove inorganic carbon (IC). Analysis is by high temperature combustion with infrared detection of CO_2. NPOC does not include volatile organic species that are purged off with IC. For samples where the majority of total carbon (TC) is comprised of IC (which is common), this method is more accurate and more reliable than the TOC by subtraction method (i.e. TC minus TIC).
Dissolved Organic Carbon by Combustion (Low Level)	E358-L Vancouver - Environmental	Water	APHA 5310 B (mod)	Dissolved Organic Carbon (Non-Purgeable), also known as NPOC (dissolved), is a direct measurement of DOC after a filtered (0.45 micron) sample has been acidified and purged to remove inorganic carbon (IC). Analysis is by high temperature combustion with infrared detection of CO_2. NPOC does not include volatile organic species that are purged off with IC. For samples where the majority of DC (dissolved carbon) is comprised of IC (which is common), this method is more accurate and more reliable than the DOC by subtraction method (i.e. DC minus DIC).
Total Nitrogen by Colourimetry	E366 Vancouver - Environmental	Water	APHA 4500-P J (mod)	Total Nitrogen is determined colourimetrically using a discrete analyzer after heated persulfate digestion of the sample.
Total Phosphorus by Colourimetry (Ultra Trace)	E372-U Vancouver - Environmental	Water	APHA 4500-P E (mod).	Total Phosphorus is determined colourimetrically using a discrete analyzer after heated persulfate digestion of the sample.
Dissolved Orthophosphate by Colourimetry (Ultra Trace Level)	E378-U Vancouver - Environmental	Water	APHA 4500-P F (mod)	Dissolved Orthophosphate is determined colourimetrically on a flow analyzer on a sample that has been lab or field filtered through a 0.45 micron membrane filter. Field filtration is recommended to ensure test results represent conditions at time of sampling.
Total Metals in Water by CRC ICPMS (Trace Level)	E468 Vancouver - Environmental	Water	EPA 200.2/6020B (mod)	Water samples are digested with nitric and hydrochloric acids, and analyzed by Collision/Reaction Cell ICPMS. Method Limitation (re: Sulfur): Sulfide and volatile sulfur species may not be recovered by this method.

Analytical Methods	Method / Lab	Matrix	Method Reference	Method Descriptions
Dissolved Metals in Water by CRC ICPMS (Trace Level)	E469 Vancouver - Environmental	Water	APHA 3030B/6020B (mod)	Water samples are filtered (0.45 um), preserved with nitric acid, and analyzed by Collisiion/Reaction Cell ICPMS. Method Limitation (re: Sulfur): Sulfide and volatile sulfur species may not be recovered by this method.
Total Mercury in Water by CVAAS	E508 Vancouver - Environmental	Water	EPA 1631E (mod)	Water samples undergo a cold-oxidation using bromine monochloride prior to reduction with stannous chloride, and analyzed by CVAAS
Dissolved Mercury in Water by CVAAS	E509 Vancouver - Environmental	Water	APHA 3030B/EPA 1631E (mod)	Water samples are filtered (0.45 um), preserved with HCl, then undergo a cold-oxidation using bromine monochloride prior to reduction with stannous chloride, and analyzed by CVAAS.
Dissolved Hardness (Calculated)	EC100 Vancouver - Environmental	Water	APHA 2340B	"Hardness (as CaCO3), dissolved" is calculated from the sum of dissolved Calcium and Magnesium concentrations, expressed in CaCO3 equivalents. "Total Hardness" refers to the sum of Calcium and Magnesium Hardness. Hardness is normally or preferentially calculated from dissolved Calcium and Magnesium concentrations, because it is a property of water due to dissolved divalent cations.

Preparation Methods	Method / Lab	Matrix	Method Reference	Method Descriptions
Preparation for Ammonia	EP298 Vancouver - Environmental	Water		Sample preparation for Preserved Nutrients Water Quality Analysis.
Preparation for Total Organic Carbon by Combustion	EP355 Vancouver - Environmental	Water		Preparation for Total Organic Carbon by Combustion
Preparation for Dissolved Organic Carbon for Combustion	EP358 Vancouver - Environmental	Water	APHA 5310 B (mod)	Preparation for Dissolved Organic Carbon
Digestion for Total Nitrogen in water	EP366 Vancouver - Environmental	Water	APHA 4500-P J (mod)	Samples are heated with a persulfate digestion reagent.
Digestion for Total Phosphorus in water	EP372 Vancouver - Environmental	Water	APHA 4500-P E (mod).	Samples are heated with a persulfate digestion reagent.
Dissolved Metals Water Filtration	EP421 Vancouver - Environmental	Water	APHA 3030B	Water samples are filtered (0.45 um), and preserved with HNO3.

Preparation Methods	Method / Lab	Matrix	Method Reference	Method Descriptions
Dissolved Mercury Water Filtration	EP509 Vancouver - Environmental	Water	APHA 3030B	Water samples are filtered (0.45 um), and preserved with HCl.

This report has been prepared by Nautilus Environmental Company Inc. based on data and/or samples provided by our client and the results of this study are for their sole benefit. Any reliance on the data by a third party is at the sole and exclusive risk of that party. The results presented here relate only to the samples tested.

SUMMARY

Sample Information and Test Type

Sample IDs and Treatment	Weir at 3.10 and laboratory water amended with arsenic (As) and antimony (Sb)
Collection date	October 30, 2017 (Weir at 3.10)
Receipt date	November 1, 2017 (Weir at 3.10)
Sample test treatment preparation/amendment date	November 1, 2017 for Weir at 3.10 and laboratory water
Receipt temperature	8.8°C (Weir at 3.10)
Test types	72-h *Pseudokirchneriella subcapitata* growth inhibition

Summary of Results (amended laboratory water test)

Endpoint	µg/L As	µg/L Sb
P. subcapitata		
Growth IC25 (95% CL)	10.9 (3.8 – 90.6)	17.0 (9.3 – 121.9)
Growth IC50 (95% CL)	122.6 (92.8 – 143.6)	162.6 (121.2 – 193.4)
NOEC	3.5	8.5
LOEC	7.1	12.8

IC = Inhibition Concentration, NOEC = No Observed Effect Concentration, LOEC = Lowest Observed Effect Concentration, CL = Confidence Limits

Summary of Results (amended Weir at 3.10 test)

Endpoint	µg/L As	µg/L Sb
P. subcapitata		
Growth IC25 (95% CL)	42.7 (33.3 – 48.0)	54.3 (42.6 – 60.7)
Growth IC50 (95% CL)	74.1 (67.5 – 81.7)	95.2 (85.6 – 101.5)
NOEC	11.4	14.1
LOEC	18.7	23.2

IC = Inhibition Concentration, NOEC = No Observed Effect Concentration, LOEC = Lowest Observed Effect Concentration, CL = Confidence Limits

1.0 INTRODUCTION

Nautilus Environmental Company Inc. conducted 72-h *Pseudokirchneriella subcapitata* growth inhibition tests for Pretium Exploration. Sample Weir at 3.10 was collected on October 30, 2017 and delivered to the Nautilus Environmental laboratory in Burnaby, BC on November 1, 2017. The sample was transported in one 20-L plastic container and was received at a temperature of 8.8°C. The sample was stored in the dark at 4 ± 2°C prior to testing.

Sample Weir at 3.10 was amended with a range of arsenic (As) and antimony (Sb) concentrations, according to instructions provided by Lorax Environmental prior to testing. A concurrent test, using *P. subcapitata* laboratory control water, amended to the same arsenic and antimony concentrations as the sample, was also performed. Testing was initiated on November 1, 2017.

This report describes the results of the toxicity tests. Copies of raw laboratory data sheets and statistical analyses are provided in Appendix A. Copies of analytical chemistry analyses supplied by Lorax Environmental are provided in Appendix B. The chain-of-custody form is provided in Appendix C.

2.0 METHODS

Methods for the toxicity tests are summarized in Table 1. Testing using *P. subcapitata* was conducted according to procedure described by Environment Canada (2007).

The amended Weir at 3.10 and laboratory water test solutions were prepared at the Nautilus Environmental laboratory using an in-house concentrated arsenic stock solution, and a concentrated antimony stock solution supplied by Lorax Environmental. Aliquots of each prepared test solution were sent to ALS Environmental, Burnaby, BC for measurement of total and dissolved arsenic and antimony. Analytical results were reported directly to Lorax Environmental, and subsequently supplied to Nautilus Environmental for inclusion in the final report. Table 1 provides a summary of the nominal and total measured arsenic and antimony concentrations.

Statistical analyses for the tests were performed using CETIS (Tidepool Scientific Software, 2013). The test endpoints were calculated using total measured arsenic and antimony values, as instructed by Lorax Environmental.

Table 1. Nominal and total measured As and Sb concentrations in laboratory water and sample Weir at 3.10.

Test Treatment	µg/L As		µg/L Sb	
	Nominal	Total Measured	Nominal	Total Measured

Concentration 4	56	60.4	70	78.6
Concentration 5	112	115	141	144
Concentration 6	224	224	282	289
Concentration 7	448	461	563	573

Table 2. Summary of test conditions: 72-h *Pseudokirchneriella subcapitata* growth inhibition test.

Test species	*Pseudokirchneriella subcapitata*, strain UTCC# 37
Organism source	In-house axenic culture, obtained from Canadian Phycological Culture Center, and originally isolated from Nivelta River, Norway.
Organism age	3-to 7-day old culture in logarithmic growth phase
Test type	Static
Test duration	72 hours
Test vessel	Microplate
Test volume	220 µL
Test concentrations	Full strength sample diluted to 95.2% (v/v) with nutrients (site control), full strength sample diluted to 95.2% (v/v) with nutrients and amended with a range of seven As and Sb concentrations, plus laboratory control. Laboratory control/dilution water amended with a range of eight As and Sb concentrations, plus laboratory control.
Test replicates	4 per treatment; 8 for laboratory control and site control
Number of organisms	10,000 cells/mL
Laboratory control water	Deionized water supplemented with nutrients
Site control dilution water	Full strength sample (Weir at 3.10) diluted to 95.2% (v/v) with nutrients
Test solution renewal	None
Test temperature	24 ± 2°C
Feeding	None
Light intensity	3600 to 4400 lux
Photoperiod	24 hours light
Aeration	None
Test measurements	Test area temperature measured daily; temperature and pH measured at test initiation; pH of two control wells measured at test termination
Test protocol	Environment Canada (2007b), EPS 1/RM/25
Statistical software	CETIS Version 1.8.7
Test endpoint	Algal cell growth inhibition
Test acceptability criteria for controls	>16-fold increase in number of algal cells; CV ≤ 20%; no trend when analyzed using Mann-Kendall test
Reference toxicant	Zinc (added as $ZnCl_2$)

3.0 RESULTS

Results of the toxicity test with *P. subcapitata* are summarized in Table 3. An inhibitory effect on cell yield was observed in the laboratory water spiked with both As and Sb. Analyzing the test data for individual measured total metal, the IC25 and IC50 for arsenic were 10.9 and 122.6 µg/L As, respectively; and with respect to antimony, the IC25 value was 17.0 µg/L Sb and the IC50 value was 162.6 µg/L Sb. The arsenic NOEC for cell yield was 3.5 µg/L As and the LOEC was 7.1 µg/L As. The NOEC and LOEC values for antimony were 8.5 and 12.8 µg/L Sb, respectively.

Results of the toxicity test with *P. subcapitata* on the arsenic and antimony amended Weir at 3.19 sample are summarized in Table 4. Adverse effects on cell yield were also observed in the sample spiked with As and Sb. Note that these results were based on the combined effects of As and Sb. If analyzed for each measured total metal, the resulting IC25 and IC50 values for arsenic were 42.7 and 74.1 µg/L As, respectively; and the IC25 and IC50 values for antimony were 54.3 and 95.2 µg/L, respectively. The NOEC for arsenic was 11.4 µg/L As and the LOEC was 18.7 µg/L As. With respect to antimony, the NOEC was 14.1 µg/L Sb and the LOEC was 23.2 µg/L Sb.

Table 3. Results: 72-h *Pseudokirchneriella subcapitata* growth inhibition test (laboratory control water amended with As and Sb).

Test Treatment	Total Measured As (µg/L)	Total Measured Sb (µg/L)	Cell Yield ($x10^4$ cells/mL) (Mean ±SD)

LOEC	18.7	23.2	--

SD = Standard Deviation, IC = Inhibition Concentration, NOEC = No Observed Effect Concentration, LOEC = Lowest Observed Effect Concentration, CL = Confidence Limits

4.0 QA/QC

The health history of the test organism used in the exposures was acceptable and met the requirements of the test protocol. The tests met all control acceptability criteria and water quality parameters remained within ranges specified in the protocols throughout the tests. Uncertainty associated with the tests is best described by the standard deviation around the mean and/or the confidence intervals around the point estimates.

Results of the reference toxicant test conducted during the testing program are summarized in Table 7. Results for this test fell within the acceptable range for organism performance of mean and two standard deviation range, based on historical results obtained by the laboratory with these tests. Thus, the sensitivity of the organism used in these tests were appropriate. The reference toxicant test was performed under the same conditions as those used for the samples.

Table 5. Reference toxicant test results.

Test Species	Endpoint	Historical Mean (2 SD Range)	CV (%)	Test Date
P. subcapitata	Growth (IC50): 28.6 µg/L Zn	32.8 (26.5 – 40.6)	11	October 25, 2017

SD = Standard Deviation, CV = Coefficient of Variation, IC = Inhibition Concentration

Pseudokirchneriella subcapitata Summary Sheet

Client: Lorax / Pretium Exploration
Start Date: Nov 2/17
Work Order No.: 171295
Set up by: MG.

Sample Information:

Sample ID: Lab control spiked with Sb and As.
Sample Date: Nov 2/17
Date Received: Nov 2/17
Sample Volume: n/a

Test Organism Information:

Culture Date: Oct 27/17
Age of culture (Day 0): 6d

Zinc Reference Toxicant Results:

Reference Toxicant ID: SC162
Stock Solution ID: 17Zn03
Date Initiated: Oct 25/17

72-h IC50 (95% CL): 28.6 (22.8 - 34.9) ug/L Zn

72-h IC50 Reference Toxicant Mean and Range: 32.8 (26.5 - 40.6) ug/L Zn CV (%): 11

Test Results:

ug/L As	Algal Growth
IC25 ~~%(v/v)~~ mg/L (95% CL)	10.9 (3.8 - 90.6)
IC50 ~~%(v/v)~~ ug/L As mg/L (95% CL)	122.6 (92.8 - 143.6)
NOEC	3.5
LOEC	7.1

Pseudokirchneriella subcapitata Summary Sheet

Client: LorGx / Pretium Exploration
Start Date: Nov 2/17
Work Order No.: 171295
Set up by: MG

Sample Information:

Sample ID: Weir at 3.10 spiked with Sb and As.
Sample Date: Oct 30/17
Date Received: Nov 1/17
Sample Volume: 1x20L

Test Organism Information:

Culture Date: Oct 27/17
Age of culture (Day 0): 6d

Zinc Reference Toxicant Results:

Reference Toxicant ID: SC162
Stock Solution ID: 17Zn03
Date Initiated: Oct 25/17

72-h IC50 (95% CL): 28.6 (22.8 - 34.9) µg/L Zn

72-h IC50 Reference Toxicant Mean and Range: 32.8 (26.5 - 40.6) µg/L Zn CV (%): 11

Test Results:

µg/L As	Algal Growth
IC25 ~~%(v/v)~~ mg (95% CL)	42.7 (33.3 - 48.0)
IC50 ~~%(v/v)~~ mg (95% CL)	74.1 (67.5 - 81.7)
µg/L As. NOEC	11.4
LOEC	18.7

Reviewed by: JOL

Reference Information

QC Samples with Qualifiers & Comments:

QC Type Description	Parameter	Qualifier	Applies to Sample Number(s)
Matrix Spike	Magnesium (Mg)-Dissolved	MS-B	L2018129-1, -10, -11, -12, -13, -14, -15, -16, -17, -2, -3, -4, -5, -6, -7, -8, -9
Matrix Spike	Manganese (Mn)-Dissolved	MS-B	L2018129-1, -10, -11, -12, -13, -14, -15, -16, -17, -2, -3, -4, -5, -6, -7, -8, -9
Matrix Spike	Sodium (Na)-Dissolved	MS-B	L2018129-1, -10, -11, -12, -13, -14, -15, -16, -17, -2, -3, -4, -5, -6, -7, -8, -9
Matrix Spike	Magnesium (Mg)-Total	MS-B	L2018129-1, -10, -11, -12, -13, -14, -15, -16, -17, -2, -3, -4, -5, -6, -7, -8, -9
Matrix Spike	Manganese (Mn)-Total	MS-B	L2018129-1, -10, -11, -12, -13, -14, -15, -16, -17, -2, -3, -4, -5, -6, -7, -8, -9
Matrix Spike	Sodium (Na)-Total	MS-B	L2018129-1, -10, -11, -12, -13, -14, -15, -16, -17, -2, -3, -4, -5, -6, -7, -8, -9

Qualifiers for Individual Parameters Listed:

Qualifier	Description
MS-B	Matrix Spike recovery could not be accurately calculated due to high analyte background in sample.

Test Method References:

ALS Test Code	Matrix	Test Description	Method Reference**
ALK-TITR-VA	Water	Alkalinity Species by Titration	APHA 2320 Alkalinity

This analysis is carried out using procedures adapted from APHA Method 2320 "Alkalinity". Total alkalinity is determined by potentiometric titration to a pH 4.5 endpoint. Bicarbonate, carbonate and hydroxide alkalinity are calculated from phenolphthalein alkalinity and total alkalinity values.

CL-IC-N-VA	Water	Chloride in Water by IC	EPA 300.1 (mod)

Inorganic anions are analyzed by Ion Chromatography with conductivity and/or UV detection.

EC-PCT-VA	Water	Conductivity (Automated)	APHA 2510 Auto. Conduc.

This analysis is carried out using procedures adapted from APHA Method 2510 "Conductivity". Conductivity is determined using a conductivity electrode.

EC-SCREEN-VA	Water	Conductivity Screen (Internal Use Only)	APHA 2510

Qualitative analysis of conductivity where required during preparation of other tests - e.g. TDS, metals, etc.

HARDNESS-CALC-VA	Water	Hardness	APHA 2340B

Hardness (also known as Total Hardness) is calculated from the sum of Calcium and Magnesium concentrations, expressed in CaCO3 equivalents. Dissolved Calcium and Magnesium concentrations are preferentially used for the hardness calculation.

MET-D-CCMS-VA	Water	Dissolved Metals in Water by CRC ICPMS	APHA 3030B/6020A (mod)

Water samples are filtered (0.45 um), preserved with nitric acid, and analyzed by CRC ICPMS.

Method Limitation (re: Sulfur): Sulfide and volatile sulfur species may not be recovered by this method.

MET-T-CCMS-VA	Water	Total Metals in Water by CRC ICPMS	EPA 200.2/6020A (mod)

Water samples are digested with nitric and hydrochloric acids, and analyzed by CRC ICPMS.

Method Limitation (re: Sulfur): Sulfide and volatile sulfur species may not be recovered by this method.

NH3-F-VA	Water	Ammonia in Water by Fluorescence	J. ENVIRON. MONIT., 2005, 7, 37-42, RSC

This analysis is carried out, on sulfuric acid preserved samples, using procedures modified from J. Environ. Monit., 2005, 7, 37 - 42, The Royal Society of Chemistry, "Flow-injection analysis with fluorescence detection for the determination of trace levels of ammonium in seawater", Roslyn J. Waston et al.

NO2-L-IC-N-VA	Water	Nitrite in Water by IC (Low Level)	EPA 300.1 (mod)

Inorganic anions are analyzed by Ion Chromatography with conductivity and/or UV detection.

NO3-L-IC-N-VA	Water	Nitrate in Water by IC (Low Level)	EPA 300.1 (mod)

Inorganic anions are analyzed by Ion Chromatography with conductivity and/or UV detection.

P-T-PRES-COL-VA	Water	Total P in Water by Colour	APHA 4500-P Phosphorus

This analysis is carried out using procedures adapted from APHA Method 4500-P "Phosphorus". Total Phosphorus is determined colourimetrically after persulphate digestion of the sample.
Samples with very high dissolved solids (i.e. seawaters, brackish waters) may produce a negative bias by this method. Alternate methods are available for these types of samples.

Reference Information

Arsenic (5+), at elevated levels, is a positive interference on colourimetric phosphate analysis.

SO4-IC-N-VA	Water	Sulfate in Water by IC	EPA 300.1 (mod)

Inorganic anions are analyzed by Ion Chromatography with conductivity and/or UV detection.

** ALS test methods may incorporate modifications from specified reference methods to improve performance.

The last two letters of the above test code(s) indicate the laboratory that performed analytical analysis for that test. Refer to the list below:

Laboratory Definition Code	Laboratory Location
VA	ALS ENVIRONMENTAL - VANCOUVER, BRITISH COLUMBIA, CANADA

Chain of Custody Numbers:

GLOSSARY OF REPORT TERMS

Surrogate - A compound that is similar in behaviour to target analyte(s), but that does not occur naturally in environmental samples. For applicable tests, surrogates are added to samples prior to analysis as a check on recovery.
mg/kg - milligrams per kilogram based on dry weight of sample.
mg/kg wwt - milligrams per kilogram based on wet weight of sample.
mg/kg lwt - milligrams per kilogram based on lipid-adjusted weight of sample.
mg/L - milligrams per litre.
< - Less than.
D.L. - The reported Detection Limit, also known as the Limit of Reporting (LOR).
N/A - Result not available. Refer to qualifier code and definition for explanation.

Test results reported relate only to the samples as received by the laboratory.
UNLESS OTHERWISE STATED, ALL SAMPLES WERE RECEIVED IN ACCEPTABLE CONDITION.
Analytical results in unsigned test reports with the DRAFT watermark are subject to change, pending final QC review.

SUMMARY

Sample Information and Test Type

Sample ID and Treatment	BJ 3.10 (site water) and laboratory water amended with antimony (Sb), arsenic (As), or ammonia (NH_3-N)
Sample collection date	June 25, 2018 (BJ 3.10)
Sample receipt date	June 27, 2018 (BJ 3.10)
Sample and laboratory water Treatment amendment date	July 3, 2018 for *Pseudokirchneriella subcapitata* test and *Ceriodaphnia dubia* test
	July 4, 2018 for *Chironomus dilutus* test
Sample receipt temperature	13.6°C
Test types	72-h *Pseudokirchneriella subcapitata* growth inhibition
	10-d *Chironomus dilutus* survival and growth
	Ceriodaphnia dubia survival and reproduction

Summary of Results

Endpoints	µg/L (95% CL)			
	Site Water (BJ 3.10)		Laboratory Water	
	Sb	As	Sb	As
P. subcapitata				
Growth IC25	>1220	110.0 (99.3 – 119.8)	675.5 (627.7 – 713.6)	49.9 (6.4 – 59.3)
Growth IC50	>1220	200.5 (184.3 – 214.2)	854.6 (811.8 – 893.5)	94.0 (82.8 – 104.0)

Growth IC25	>93.1	>97.0
Growth IC50	>93.1	>97.0
NOEC (survival, dry weight)	48.1, 48.1	50, 50
LOEC (survival, dry weight)	93.1, >48.1	97, >50

LC = Lethal Concentration, IC = Inhibition Concentration, CL = Confidence Limits,
NOEC = No Observed Effect Concentration, LOEC = Lowest Observed Effect Concentration

Endpoints	mg/L (95% CL)	
	Site Water (BJ 3.10) NH_3-N	Laboratory Water NH_3-N
C. dubia		
Survival LC50	33.9 (28.1 – 41.0)	34.7 (24.3 – 49.6)
Reproduction IC25	24.0 (18.3 - 25.9)	14.2 (11.3 - 15.6)
Reproduction IC50	30.4 (28.1 - 31.9)	18.8 (16.5 - 20.2)
NOEC (survival, reproduction)	23.9, 23.9	24.3, 12.3
LOEC (survival, reproduction)	48.4, >23.9	>24.3, 24.3

LC = Lethal Concentration, IC = Inhibition Concentration, CL = Confidence Limits
NOEC = No Observed Effect Concentration, LOEC = Lowest Observed Effect Concentration

1.0 INTRODUCTION

Nautilus Environmental Company Inc. conducted toxicity tests for Pretivm Resources Inc. evaluating toxicity effects of antimony (Sb) and arsenic (As) on *Pseudokirchneriella subcapitata* and ammonia (NH_3-N) on *Chironomus dilutus* and *Ceriodaphnia dubia*. Site water BJ 3.10 was amended with a series of Sb, As, and NH_3-N concentrations, according to instructions provided by Pretivm Resources Inc. prior to testing. Concurrent tests using laboratory control water, amended to the same Sb, As and NH_4 concentrations as the site water, were also performed.

BJ 3.10 was collected on June 25, 2018 and delivered to the Nautilus Environmental laboratory in Burnaby, BC on June 27, 2018. The sample was transported in two 20-L plastic containers which were received at 13.6°C. The sample was stored in the dark at 4 ± 2°C prior to testing. The laboratory water was prepared in-house and was the same water used to culture the test species and/or used for testing at Nautilus Environmental. The following toxicity tests were performed:

- 72-h *Pseudokirchneriella subcapitata* growth inhibition
- 10-d *Chironomus dilutus* survival and growth
- *Ceriodaphnia dubia* survival and reproduction

Testing for *P. subcapitata* and *C. dubia* was initiated on July 3, 2018, and testing for *C. dilutus* was initiated on July 4, 2018. This report describes the results of these toxicity tests. Copies of raw laboratory data sheets and statistical analyses for each test species are provided in Appendices A to C. The analytical chemistry and chain-of-custody form are provided in Appendix D and E respectively.

2.0 METHODS

Methods for the toxicity tests are summarized in Tables 4 to 6. Testing for *P. subcapitata* and *C. dubia* was conducted according to procedures described by Environment Canada (2007a and 2007b). For the *C. dubia* test, BJ 3.10 was hardness-adjusted to match the hardness of the laboratory control water and was used as site-control and dilution water. Testing for *C. dilutus* was conducted according to procedures described by Environmental Canada (1997) with the following modifications: i) 200 mL of test solution was used in each replicate; ii) four replicates were used in each concentration; iii) total ammonia of overlying water was only measured at test initiation; iv) a pinch of clean sand was added into each test jar as substrate.

The Sb-, As- and NH_3-N-amended BJ 3.10 and laboratory water test solutions were prepared at the Nautilus Environmental laboratory. Analytical results were reported to Nautilus Environmental for inclusion in the final report. Tables 1 to 3 provide a summary of the nominal and total measured arsenic, antimony and ammonia concentrations. The total measured concentrations of Sb, As and NH_3-N were used to estimate LC50, IC25, IC50, NOEC and LOEC values. Statistical analyses for all the tests were performed using CETIS (Tidepool Scientific Software, 2013). Tests performed in site water used site water as the control value and tests performed in laboratory water used lab water as the control value for statistical analysis.

Table 4. Summary of test conditions: *Pseudokirchneriella subcapitata* growth inhibition test.

Test species	*Pseudokirchneriella subcapitata*, strain CPCC# 37
Organism source	In-house axenic culture, obtained from Canadian Phycological Culture Center, and originally isolated from Nivelta River, Norway.
Organism age	3-to 7-day old culture in logarithmic growth phase
Test type	Static
Test duration	72 hours
Test vessel	Microplate
Test volume	220 µL
Test concentrations	Eight concentrations, plus laboratory control/site control (BJ 3.10)
Test replicates	4 per treatment; 8 for laboratory control
Number of organisms	10,000 cells/mL
Control/dilution water	Deionized water supplemented with nutrients/site control (BJ 3.10)
Test solution renewal	None
Test temperature	24 ± 2°C
Feeding	None
Light intensity	3600 to 4400 lux
Photoperiod	24 hours light
Aeration	None
Test measurements	Test area temperature measured daily; temperature and pH measured at test initiation; pH of two control wells measured at test termination
Test protocol	Environment Canada (2007a), EPS 1/RM/25
Statistical software	CETIS Version 1.8.7
Test endpoints	Algal cell growth inhibition
Test acceptability criteria for controls	>16-fold increase in number of algal cells; CV ≤ 20%; no trend when analyzed using Mann-Kendall test
Reference toxicant	Zinc (added as $ZnSO_4$)

Table 5. Summary of test conditions: *Chironomus dilutus* survival and growth test.

Test species	*Chironomus dilutus*
Organism source	Aquatic BioSystems, Fort Collins, CO
Organism age	Third instar
Test type	Static
Test duration	10 days
Test vessel	375-mL glass container
Test volume	200 mL overlying water
Test replicates	4 replicates per concentration
Number of organisms	10 per replicate
Control/dilution water	Reconstituted moderately-hard water/site control (BJ 3.10)
Test solution renewal	None
Test temperature	23 ± 1°C
Feeding	6 mg of Tetramin per replicate daily
Light intensity	500 to 1000 lux at water surface
Photoperiod	16 hours light/8 hours dark
Aeration	Continuous gentle aeration
Test measurements	Temperature, dissolved oxygen, pH and conductivity of overlying water measured daily; hardness and alkalinity at test initiation and termination; total ammonia of overlying water measured at test initiation
Test protocol	Environment Canada (1997), EPS 1/RM/32
Statistical software	CETIS Version 1.8.7
Test endpoints	Survival and dry weight
Test acceptability criteria for controls	≥70% survival and ≥0.6 mg/worm dry weight
Reference toxicant	Potassium chloride (KCl)

Table 6. Summary of test conditions: *Ceriodaphnia dubia* survival and reproduction test.

Test species	*Ceriodaphnia dubia*
Organism source	In-house culture
Organism age	<24 hour old neonates, produced within a 12 hour window
Test type	Static-renewal
Test duration	7 ± 1 day
Test vessel	20-mL glass test tube
Test volume	15 mL
Test solution depth	10 cm
Test concentrations	Seven concentrations, plus laboratory control/site control (BJ 3.10)
Test replicates	10 per treatment
Number of organisms	1 per replicate
Control/dilution water	Laboratory water: 20% Perrier water and 80% deionized water + 5 µg/L Se and 2 µg/L vitamin B1 Site water (BJ 3.10): hardness adjusted to match the hardness of the laboratory water
Test solution renewal	Daily (100% renewal)
Test temperature	25 ± 1°C
Feeding	Daily with *Pseudokirchneriella subcapitata* and YCT (3:1 ratio)
Light intensity	100 to 600 lux at water surface
Photoperiod	16 hours light / 8 hours dark
Aeration	None
Test measurements	Temperature, dissolved oxygen, pH and conductivity measured daily; hardness and alkalinity of undiluted sample measured at test initiation; survival and reproduction checked daily
Test protocol	Environment Canada (2007b), EPS 1/RM/21
Statistical software	CETIS Version 1.8.7
Test endpoints	Survival and reproduction
Test acceptability criteria for controls	≥80% survival; ≥15 young per surviving control producing three broods; ≥60% of controls producing three or more broods; no ephippia present
Reference toxicant	Sodium chloride (NaCl)

3.0 RESULTS

Results of the toxicity tests are summarized in Tables 7 to 10.

In the *P. subcapitata* growth inhibition test with Sb (Table 7), inhibitory effects on cell yield were observed in the site water. The NOEC and LOEC were 599 and 1220 µg/L Sb, respectively; the IC25 and IC50 were >1220 µg/L Sb. Inhibitory effects were observed on cell yield in laboratory water. The IC25 and IC50 for cell yield were 675.5 and 854.6 µg/L Sb, respectively. The NOEC and LOEC on cell yield were 81.5 and 159.0 µg/L Sb in laboratory water, respectively.

In the *P. subcapitata* growth inhibition test with As (Table 8), inhibitory effects on cell yield were observed in site water. The IC25 and IC50 for cell yield were 110.0 and 200.5 µg/L As, respectively. The NOEC and LOEC on cell yield were 54.7 and 103.0 µg/L As. In the laboratory water, inhibitory effects on cell yield were also observed. The IC25 and IC50 for cell yield were 49.9 and 94.0 µg/L As, respectively. The NOEC and LOEC on cell yield were 13.3 and 25.5 µg/L As, respectively.

In the *C. dilutus* survival and growth test with NH_3-N (Table 9), adverse effects were observed on survival in both the site water and laboratory water, which resulted in an LC50 of 73.5 and 81.5 mg/L NH_3-N, respectively. The NOEC and LOEC for survival were 48.1 and 93.1 mg/L NH_3-N in site water and 50 and 97 mg/L NH_3-N in laboratory water, respectively. There were no adverse effects observed on dry weight in neither the laboratory water nor the site water. The NOEC and LOEC for dry weight were 48.1 and >48.1 mg/L NH_3-N in site water and 50.0 and >50.0 mg/L NH_3-N in laboratory water, respectively.

In the *C. dubia* survival and growth test with NH_3-N (Table 10), adverse effects were observed on survival and reproduction in both the laboratory water and the site water. In the site water, the LC50 was estimated to be 33.9 mg/L NH_3-N, and the IC25 and IC50 were estimated to be 24.0 and 30.4 mg/L NH_3-N, respectively. The NOEC and LOEC on survival were 23.9 and 48.4 mg/L NH_3-N, and on reproduction were 23.9 and >23.9 mg/L NH_3-N, respectively. In the laboratory water, the LC50 was estimated to be 34.7 mg/L NH_3-N, and the IC25 and IC50 were estimated to be 14.2 and 18.8 mg/L NH_3-N, respectively. The NOEC and LOEC on survival were 24.3 and >24.3 mg/L NH_3-N, and on reproduction were 12.3 and 24.3 mg/L NH_3-N, respectively.

4.0 QA/QC

The health history of the test organisms used in the exposure was acceptable and met the requirements of the Environment Canada protocols. The tests met all control acceptability criteria and water quality parameters remained within ranges specified in the protocols throughout the tests. There were no deviations from the test methodology except that the testing with all species was initiated outside of the three day holding time. In addition, the *C. dilutus* test was conducted in water only, instead of sediment, following the procedures described in the Methods section.

Uncertainty associated with the tests are best described by the standard deviation around the mean and/or the confidence intervals around the point estimates. Results of the reference toxicant tests conducted during the testing program are summarized in Table 11. Results for these tests fell within the range for organism performance of the mean and two standard deviations, based on historical results obtained by the laboratory with these tests. Thus, the sensitivity of the organisms used in these tests was appropriate. The reference toxicant tests were performed under the same conditions as those used for the sample.

Table 11. Reference toxicant test results.

Test Species	Endpoint	Historical Mean (2 SD Range)	CV (%)	Test Date
P. subcapitata	Growth (IC50): 34.1 µg/L Zn	31.4 (26.1 – 37.8)	10	June 29, 2018
C. dilutus	Survival (LC50): 6.6 g/L KCl	5.1 (2.8 – 9.1)	34	July 4, 2018
C. dubia	Survival (LC50): 2.1 g/L NaCl	2.0 (1.8 – 2.3)	6	July 4, 2018
	Reproduction (IC50): 1.4 g/L NaCl	1.3 (0.8 – 1.9)	24	

SD = Standard Deviation, CV = Coefficient of Variation, LC = Lethal Concentration, IC = Inhibition Concentration

Pseudokirchneriella subcapitata Summary Sheet

Client: Lorax (Pretium)
Work Order No.: 181047

Start Date: July 03/18
Set up by: MG

Sample Information:

Sample ID: Lab water amended with Sb
Sample Date: July 3/18
Date Received: July 3/18
Sample Volume: n/a

Test Organism Information:

Culture Date: June 29/18
Age of culture (Day 0): 4d

Zinc Reference Toxicant Results:

Reference Toxicant ID: SC171
Stock Solution ID: 18Zn 01
Date Initiated: June 29/18

72-h IC50 (95% CL): 34.1 (29.4 - 37.0) ug/L Zn

72-h IC50 Reference Toxicant Mean and Range: 31.4 (26.1-37.8) ug/L Zn CV (%): 10

Test Results:

ug/L Sb	Algal Growth
IC25 ~~%(v/v)~~ mg (95% CL)	675.5 (627.7 - 713.6)
IC50 ~~%(v/v)~~ ug/L Sb mg (95% CL)	854.6 (811.8 - 893.5)

APPENDIX C – *Ceriodaphnia dubia* Toxicity Test Data

Ceriodaphnia dubia Summary Sheet

Client: Lotrax (Pratum)
Work Order No.: 181138

Start Date/Time: July 3/18 @ 1700h
Set up by: [illegible]

Sample Information:

Sample ID: BJ 3-10
Sample Date: June 25/18
Date Received: June 27/18
Sample Volume: 2 x 20L

Test Validity Criteria:

1) Mean survival of first generation controls is ≥80 %
2) At least 60% of controls have produced three broods within 8 days
3) An average of ≥15 live young produced per surviving female in the control solutions during the first three broods.
4) Invalid if ephippia observed in any control solution at any time.

WQ Ranges:

T (°C) = 25 ± 1; DO (mg/L) = 4.0 to 8.4 ; pH = 6.0 to 9.0

Test Organism Information:

Broodstock No.: BB062018 A & B
Age of young (Day 0): <24-h (within 8-h)
Avg No. young in first 3 broods of previous 7 d: 32
Mortality (%) in previous 7 d: 5
Individual female # used ≥8 young on test day: 3-10, 32, 35-40

NaCl Reference Toxicant Results:
